A FRAMEWORK FOR TEACHING STATISTICS
WITHIN THE K-12 MATHEMATICS CURRICULUM

[Draft version 1/31/05]

Introduction

The Ultimate Goal: Statistical Literacy

Every morning the newspaper or other media confront us with statistical information on topics which range from the economy to education, from movies to sports, from food to medicine, from public opinion to social behavior; such information informs decisions in our personal lives and enables us to meet our responsibilities as citizens. At work we may be confronted by quantitative information on budgets, supplies, manufacturing specifications, market demands, sales forecasts or workloads. Teachers may be confronted with educational statistics concerning student performance or their own accountability. Medical scientists must understand the statistical results of experiments used for testing the effectiveness and safety of drugs. Law enforcement professionals depend on crime statistics. If we consider changing jobs and moving to another community, then our decision can be informed by statistics about cost of living, crime rate, and educational quality.

Our lives are governed by numbers. Every high school graduate should be able to use sound statistical reasoning in order to cope intelligently with the requirements of citizenship, employment and family, and to be prepared for a healthy, happy and productive life.

Citizenship

Public opinion polls are the most visible examples of a statistical application that has an impact on our lives. In addition to informing individual citizens directly, polls are used by others in ways that affect us. The political process employs opinion polls in several ways. Candidates for office use polling to guide campaign strategy. A poll can determine a candidate’s strengths with voters, which can in turn be emphasized in the campaign. Citizens might be suspicious also that poll results might influence a candidate to take positions just because they are popular.

A citizen informed by polls needs to understand that the results were determined from a sample of the population under study, that the reliability of the results depends on how the sample was selected, and that the results are subject to sampling error. The statistically literate citizen should understand the behavior of “random” samples and be able to interpret a “margin of sampling error”.

The Federal Government has been in the statistics business from its very inception. The U.S. Census was established in 1790 to provide an official count of the population for the purpose of allocating representatives to the congress. Not only has the role of the Census Bureau greatly expanded to include the collection of a broad spectrum of socio-economic information.
data but other Federal departments produce extensive “official” statistics concerned with agriculture, health, education, environment and commerce. The information gathered by these agencies influences policy making, helps to determine priorities for government spending, and is also available for general use by individuals or private groups. Thus, statistics compiled by government agencies have a tremendous impact on the life of the ordinary citizen.

**Personal Choices**

Statistical literacy is required for daily personal choices. Statistics provide information on the composition of foods and thus inform our choices at the grocery store. Statistics help to establish the safety and effectiveness of drugs to help us choose a treatment. Statistics help to establish the safety of toys to assure that our little ones are not at risk. Our investment choices are guided by a plethora of statistical information about stocks and bonds. The Nielsen ratings decide which shows will survive on television and thus affect what is available. Many products have a previous statistical history and our choices of products can be affected by awareness of this history. The design of an automobile is aided by anthropometrics, the statistics of the human body, to enhance passenger comfort. Statistical ratings of fuel efficiency, safety and reliability are available to help us select a vehicle.

**The Workplace and Professions**

The individuals who are prepared to use statistical thinking in their jobs careers will have the opportunity to advance to more rewarding and challenging positions. A statistically competent work force will allow the United States to be more competitive in the global market place and improve its position in the international economy. An investment in statistical literacy is an investment in our nation’s economic future as well as the well-being of individuals.

Efforts to improve quality and accountability are prominent among the many ways that statistical thinking and tools can be used to enhance productivity. The competitive marketplace demands quality. Quality control practices such as the statistical monitoring of design and manufacturing processes identify where improvement can be made and lead to better product quality. Systems of accountability can help produce more effective employees and organizations, but many accountability systems now in place are not based on sound statistical principles and may, in fact, have the opposite effect from the one desired. Good accountability systems require proper use of statistical tools to determine and apply appropriate criteria.
Science

Life expectancy in the USA almost doubled during the 20th century and this rapid increase in life spans is the consequence of “science.” Science has enabled us to improve medical care and procedures, food production, and the detection and prevention of epidemics. And statistics plays a prominent role in this scientific progress.

The Federal Drug Administration requires extensive testing of drugs to determine effectiveness and side effects before they can be sold. A recent advertisement for a drug designed to reduce blood clots stated “PLAVIX, added to aspirin and your current medications, helps raise your protection against heart attack or stroke.” But the advertisement also warns that “The risk of bleeding may increase with PLAVIX...” This was determined by a clinical trial involving over 12,000 subjects. Among the 6259 taking PLAVIX + aspirin 3.7% showed major bleeding problems while only 2.7% of the 6303 taking the placebo had major bleeding. This is viewed as a “statistically significant” result.

Statistical literacy involves a healthy dose of skepticism about “scientific” findings. Is the information about side effects of PLAVIX treatment reliable? A statistically literate person should ask such questions and be able to answer them intelligently. A statistically literate high school graduate will be able to understand the conclusions from scientific investigations and to offer an informed opinion about the legitimacy of the reported results. To quote from Mathematics and Democracy: The Case for Quantitative Literacy, such knowledge “empowers people by giving them tools to think for themselves, to ask intelligent questions of experts, and to confront authority confidently. These are skills required to survive in the modern world.”

Summary

Statistical literacy is essential in our personal lives as consumers, citizens and professionals. Statistics plays a role in our health and happiness. Sound statistical reasoning skills take a long time to develop. They cannot be honed to the level needed in the modern world through one high school course. The surest way to reach the necessary skill level is to begin the educational process in the elementary grades and keep strengthening and expanding these skills throughout the middle and high school years. A statistically literate high school graduate will know how to interpret the data in the morning newspaper and will ask the right questions about statistical claims. He or she will be comfortable handling quantitative decisions that come up on the job, and will be able to make informed decision about quality of life issues.

The remainder of this document lays out a framework for educational programs designed to help students achieve this noble end.
The Case for Statistics Education

Over the past quarter century, statistics (often labeled data analysis and probability) has become a key component of the K-12 mathematics curriculum. Advances in technology and in modern methods of data analysis of the 1980’s, coupled with the data richness of society in the information age, led to the development of curriculum materials geared toward introducing statistical concepts into the school curriculum as early as the elementary grades. This grass-roots effort was given sanction by the National Council of Teachers of Mathematics (NCTM) when their influential document *Curriculum and Evaluation Standards for School Mathematics*, published in 1989, included Data Analysis and Probability as one of the five content strands. As this document and its 2000 replacement entitled *Principles and Standards for School Mathematics* became the basis for reform of mathematics curricula in many states, the acceptance of and interest in statistics as part of mathematics education gained strength. In recent years many mathematics educators and statisticians have devoted large segments of their careers to the improvement in statistics education materials and pedagogical techniques.

NCTM is not the only group calling for improved statistics education beginning at the school level. The National Assessment of Educational Progress (NAEP) is developed around the same strands as in the NCTM Standards, with data analysis and probability questions playing an increasingly prominent role in the NAEP exam.

The emerging quantitative literacy movement calls for greater emphasis on practical quantitative skills that will help assure success for high school graduates in life and work; many of these skills are statistical in nature. To quote from *Mathematics and Democracy: The Case for Quantitative Literacy* :

- Quantitative literacy, also called numeracy, is the natural tool for comprehending information in the computer age. The expectation that ordinary citizens be quantitatively literate is primarily a phenomenon of the late twentieth century.
- Unfortunately, despite years of study and life experience in an environment immersed in data, many educated adults remain functionally illiterate.
- Quantitative literacy empowers people by giving them tools to think for themselves, to ask intelligent questions of experts, and to confront authority confidently. These are the skills required to thrive in the modern world.

A recent study entitled *Ready or Not: Creating a High School Diploma That Counts* from the American Diploma Project recommends "must have" competencies needed for high school graduates "to succeed in postsecondary education or in high-performance, high-growth jobs" include, in addition to algebra and geometry, aspects of data analysis, statistics, and other applications that are vitally important for other subjects as well as for employment in today's data-rich economy.

Statistics education as proposed in this *Framework* can enable the "must have" competencies for graduates to “thrive in the modern world”.

NCTM Standards and the Framework

The main objective of this document is to provide a conceptual Framework for K-12 statistics education. The foundation for this Framework rests on the NCTM Principles and Standards for School Mathematics.

The Framework is intended to support the objectives of the NCTM Principles and Standards. It is intended to complement the NCTM recommendations, not to supplant them.

The NCTM Principles and Standards describes the statistics content strand as follows.

Data Analysis and Probability

Instructional programs from pre-kindergarten through grade 12 should enable all students to—

- formulate questions that can be addressed with data and collect, organize, and display relevant data to answer them;
- select and use appropriate statistical methods to analyze data;
- develop and evaluate inferences and predictions that are based on data;
- understand and apply basic concepts of probability.

The Data Analysis and Probability Standard recommends that students formulate questions that can be answered using data and addresses what is involved in gathering and using the data wisely. Students should learn how to collect data, organize their own or others’ data, and display the data in graphs and charts that will be useful in answering their questions. This Standard also includes learning some methods for analyzing data and some ways of making inferences and drawing conclusions from data. The basic concepts and applications of probability are also addressed, with an emphasis on the way that probability and statistics are related.

The NCTM document elaborates on these themes somewhat and provides examples of the types of lessons and activities that might be used in a classroom. Statistics, however, is a relatively new subject for many teachers who have not had an opportunity to develop sound knowledge of the principles and concepts underlying the practices of data analysis that they are now called upon to teach. These teachers do not clearly understand the difference between statistics and mathematics. They do not see the statistics curriculum for grades K-12 as a cohesive and coherent curriculum strand. These teachers may not see how the overall statistics curriculum provides a developmental sequence of learning experiences.

This Framework provides a conceptual structure for statistics education which gives a coherent picture of the overall curriculum. This structure adds to but does not replace the NCTM recommendations.
The Difference between Statistics and Mathematics

"Statistics is a methodological discipline. It exists not for itself but rather to offer to other fields of study a coherent set of ideas and tools for dealing with data. The need for such a discipline arises from the omnipresence of variability." Cobb and Moore

A major objective of statistics education is to help students develop statistical thinking. Statistical thinking, in large part, must deal with this omnipresence of variability; statistical problem solving and decision making depend on understanding, explaining and quantifying the variability in the data.

It is this focus on variability in data that sets statistics apart from mathematics.

The Nature of Variability

There are many different sources of variability in data. Some of the important sources are described below.

Measurement Variability

Repeated measurements on the same individual vary. Sometimes two measurements vary because the measuring device produces unreliable results, like when we try to measure a large distance with a small ruler. Other times variability results from changes in the system being measured. For example, even with a very precise measuring device your recorded blood pressure would differ from one moment to the next.

Natural Variability

Variability is inherent in nature. Individuals are different. When we measure the same quantity across several individuals we are bound to get some differences in the measurements. Although some of this may be due to our measuring instrument, most of it is simply due to the fact that individuals differ. People naturally have different heights, different aptitudes and abilities, or different opinions and emotional responses. When we measure any one these traits we are bound to get variability in the measurements. Different seeds for the same variety of bean will grow to different sizes when subjected to the same environment because no two seeds are exactly alike; there is bound to be variability from seed to seed in the measurements of growth.

Induced Variability

If we plant one pack of bean seeds in one field, and another pack of seeds in another location with a different climate, then an observed difference in growth among the seeds in one location with those in the other might be due to inherent differences in the seeds (natural variability) or the observed difference might be due to the fact that the locations are not the same. If one type of fertilizer is used on one field and another type on the other, then observed differences might be due to the difference in fertilizers. For that
matter, the observed difference might be due to a factor that we haven't even thought about. A more carefully designed experiment can help us to determine the effects of different factors.

This one basic idea, comparing natural variability to the variability induced by other factors, forms the heart of modern statistics. It has allowed medical science to conclude that some drugs are effective and safe, where as others are ineffective or have harmful side effects. It has been employed by agricultural scientists to demonstrate that a variety of corn grows better in one climate than another, that one fertilizer is more effective than another, or one type of feed is better for beef cattle than another.

**Sampling Variability**

In a voter poll, it seems reasonable to use the proportion of voters surveyed (a sample) as an estimate of the unknown proportion of all voters who support a particular candidate. But if a second sample of the same size is used, it is almost certain that there would not be the same proportion of voters in the sample who support the candidate. The value of the proportion will vary from sample to sample. This is called sampling variability. So what is to keep one sample from estimating that the true proportion is .60 and another from saying it is .40 . This is possible but unlikely if proper sampling techniques are used. Poll results are useful because these techniques can assure that unacceptable differences among samples are quite unlikely.

**The Role of Context**

"The focus on variability naturally gives statistics a particular content that sets it apart from mathematics itself and from other mathematical sciences, but there is more than just content that distinguishes statistical thinking from mathematics. Statistics requires a different kind of thinking, because data are not just numbers, they are numbers with a context."

Cobb and Moore

Many mathematics problems arise from applied contexts, but the context is removed to reveal mathematical patterns.

Statisticians, like mathematicians, look for patterns, but the meaning of the patterns depends on the context.

"In mathematics, context obscures structure. In data analysis, context provides meaning."

Cobb and Moore

A graph, which appears occasionally in the business section of newspapers, shows a plot of the Dow Jones Industrial Average (DJIA) over a ten year period. The variability of stock prices draws the attention of an investor. This stock index may go up or down over some intervals of time, may fall or rise sharply over short a period, In context the graph
raises questions. A serious investor is not only interested in when or how rapidly the index goes up or down, but also why. What was going on in the world when the market went up, what was going on when it went down. But strip away the context. Remove time (years) from the horizontal axis and call it "X", remove stock value (DJIA) from the vertical axis and call it "Y", and there remains a graph of very little interest or mathematical content!

**Probability**

*Probability is a tool for statistics*

Probability is an important part of any mathematical education. It is a part of mathematics that enriches the subject as a whole by its interactions with other uses of mathematics. Probability is an essential tool in applied mathematics and mathematical modeling. It is also an essential tool in statistics.

But the use of probability as a mathematical model and the use of probability as a tool in statistics employ not only different approaches but different kinds of reasoning. Two problems and the nature of the solutions will illustrate the difference.

Problem 1

Assume a coin is "fair."

Question: If we toss the coin 5 times, how many heads will we get?

Problem 2

You pick up a coin.

Question: Is this a fair coin?

Problem 1 is mathematical probability problem.
Problem 2 is a statistics problem which can use the mathematical probability model determined in problem 1 as a tool to seek a solution.

The answer to neither question is deterministic. Coin tossing produces random outcomes which suggest that the answer is probabilistic. The solution to problem 1 starts with the assumption that the coin is fair and proceeds to logically deduce the numerical probabilities for each possible number of heads 0, 1, ..., 5.

The solution to problem 2 starts with an unfamiliar coin—we don't know if it is fair or biased. The search for an answer is experimental—toss the coin and see what happens. Examine the resulting data to see if it looks like it came from a fair coin or a biased coin. There are several possible approaches, including: Toss the coin 5 times and record the number of heads. Then do it again: Toss the coin 5 times and record the number of heads. Repeat 100 times. Compile the frequencies of outcomes for each possible number of heads. Compare these results to the frequencies predicted by the mathematical model for
a fair coin in problem 1. If the empirical frequencies from the experiment are quite
dissimilar from those predicted by the mathematical model for a fair coin and are not
likely to be caused by random variation in coin tosses, then we conclude the coin is not
fair. In this case we *induce* an answer by making a general conclusion from observations
of experimental results.

**Probability and Chance Variability**

Two important uses of "randomization" in statistical work occur in sampling and
experimental design. When sampling we "select at random" and in experiments we
"randomly assign individuals to different treatments." Randomization does much more
than just remove bias in selections and assignments. Randomization leads to chance
variability in outcomes which can be described with probability models.

The probability of something says about what percentage of the time it is expected to
happen when the basic process is repeated over and over again.

Probability theory does not say very much about one toss of the coin; it makes
predictions about the long-run behavior of the coin tosses.

Probability tells us little about the consequences of random selection for one sample but
describes the variation we expect to see in samples when the sampling process is repeated
a large number of times.

Probability tells us little about the consequences of random assignment for one
experiment but describes the variation we expect to see in the results when the
experiment is replicated a large number of times.

When randomness is present, the statistician wants to know if the observed result is due
to chance, or something else? This is the idea of statistical significance.

**The role of mathematics in statistics education**

The evidence that statistics is different from mathematics is not presented to argue that
mathematics is not important to statistics education or that statistics education should not
be a part of mathematics education. To the contrary, statistics education becomes
increasingly mathematical as the level of understanding goes up.

But data collection design, exploration of data, and the interpretation of results should be
emphasized in statistics education for statistical literacy. These are heavily dependent on
context, but at the introductory level involve limited formal mathematics.

Probability plays an important role in statistical analysis, but formal mathematical
probability should have its own place in the curriculum. Pre-college statistics education
should emphasize the ways that probability is used in statistical thinking; an intuitive
grasp of probability will suffice at these levels.
The Framework

Underlying Principles

Statistical Problem Solving
Statistical problem solving is an investigative process that involves four components:

Formulate Questions
• clarify the problem at hand
• formulate one (or more) questions that can be answered with data

Collect Data
• design a plan to collect appropriate data
• employ the plan to collect the data

Analyze Data
• select appropriate graphical or numerical methods
• use these methods to analyze the data

Interpret Results
• interpret the analysis
• relate the interpretation to the original question.

The Role of Variability in the Problem Solving Process

Formulate Question
Anticipating Variability - Making the statistics question distinction

The formulation of a statistics question requires an understanding of the difference between a question which anticipates a deterministic answer and a question which anticipates an answer based on data which vary.

The question "How tall am I" will be answered with a single height. It is not a statistics question. The question "How tall are adult men in the USA?" would not be a statistics question if all these men were exactly the same height! The fact that there are differing heights, however, implies that we anticipate an answer based on measurements of height which vary. This is a statistics question.

The poser of the question "How does sunlight affect the growth of a plant?" should anticipate that the growth of two plants of the same type exposed to the same sunlight will likely differ. This is a statistics question.

The anticipation of variability is the basis for understanding of the statistics question distinction; these are required for proper question formulation.
Collect Data

Acknowledging Variability - Designing for differences

Data collection designs must acknowledge variability in data and frequently are intended to reduce variability. Random sampling is intended to reduce the differences between sample and population, and the sample size influences the effect of sampling variability (error). Experimental designs are chosen to acknowledge the differences between groups subjected to different treatments. Random assignment to the groups is intended to reduce differences between the groups due to factors which are not manipulated in the experiment. Some experimental designs pair subjects so that they are similar. Twins are frequently paired in medical experiments so that observed differences might be more likely attributed to the difference in treatments rather than differences in the subjects.

The understanding of data collection designs which acknowledge differences is required for effective collection of data.

Analyze Data

Accounting of Variability Using Distributions

The main purpose of statistical analysis is to give an accounting of the variability in the data. When results of an election poll state that "42% of those polled support a particular candidate with margin of error +/- 3% at the 95% confidence level", the focus is on sampling variability. The poll gives an estimate of the support among all voters. The margin of error indicates how far the sample result (42% +/− 3%) might differ from the actual percentage of all voters who support the candidate. The confidence level tells us how often estimates produced by the method employed will produce correct results. This analysis is based on the distribution of estimates from repeated random sampling.

When test scores are described as "normally distributed with mean 450 and standard deviation 100" the focus is on how the scores differ from the mean. The normal distribution describes a bell-shaped pattern of scores and the standard deviation indicates the level of variation of the scores from the mean.

Accounting of variability with the use of distributions is the key idea in the analysis of data.
Interpret Results

Allowing for Variability

Looking beyond the data

Statistical interpretations are made in the presence of variability and must allow for it. The result of an election poll must be interpreted as an estimate which can vary from sample to sample. The generalization of the poll results to the entire population of voters looks beyond the sample of voters surveyed and must allow for the possibility of variability of results among different samples. The results of a randomized comparative medical experiment must be interpreted in the presence of variability due to the fact that different individuals respond differently to the same treatment as well as the variability due to randomization. The generalization of the results looks beyond the data collected from the subjects who participated in the experiment and must allow for these sources of variability.

Looking beyond the data to make generalizations must allow for variability in the data.

Maturing over Levels

The mature statistician understands the role of variability in the statistical problem solving process. At the point of question formulation, the statistician anticipates the data collection, the nature of the analysis, and the possible interpretations, all of which must consider possible sources of variability. In the end, the mature practitioner reflects upon all aspects of data collection and analysis as well as the question itself when interpreting results. Likewise he links data collection and analysis to each other and the other two components.

The beginning student cannot be expected to make all of these linkages. They require years of experience as well as training. Statistical education should be viewed as a developmental process. To meet the proposed goals, this report will provide a framework for statistical education over three levels. If the goal were to produce a mature practicing statistician, there would certainly be several levels beyond these. There is no attempt to tie these levels to specific grade levels.

The Framework uses three developmental levels, A, B, and C. Although these three levels may parallel grade levels, they are based on development, not age. Thus, a middle school student who has had no prior experience with statistics will need to begin with Level A concepts and activities before moving to Level B. This holds true for a secondary student as well - if a student hasn't had Level A and B experiences prior to high school, then it is not appropriate to jump into Level C expectations. The learning is more teacher driven at level A, but becomes student driven at Levels B and C.
The *Framework Model*

The conceptual structure for statistics education is provided in the two dimensional model shown in Figure **. One dimension is defined by the problem solving process components plus the nature of the variability considered and how we focus on variability. The second dimension is comprised of the three developmental levels.

Each of the first four rows describes a process component as it develops across levels. The fifth row indicates the nature of the variability considered at a given level. It is understood that work at Level B assumes and develops further the concepts from Level A, and likewise Level C assumes and uses concepts from the lower levels.

Reading down a column will describe a complete problem investigation for a particular level along with the nature of the variability considered.

Illustrations
All four steps of the problem solving process are used at all three levels, but the depth of understanding and sophistication of methods used increases across the levels A, B, C. This maturation in understanding the problem solving process and its underlying concepts is paralleled by an increasing complexity in the role of variability. The illustrations of learning activities given here are intended to clarify the differences across the developmental levels for each component of the problem solving process. A later section in this report will give illustrations of the complete problem solving process for learning activities at each level.

Formulate Question

Example 1
A: How long are the words on this page?
B: Are the words in a chapter of a fifth grade book longer than the words in a chapter of a third grade book?
C: Do fifth grade books use longer words than third grade books?

Example 2
A: What type of music is most popular among students in our class?
B: How do the favorite types of music compare among different classes?
C: What type of music is most popular among students in our school?

Example 3
A: In our class, are the heights and arm spans of students approximately the same?
B: Is the relationship between arm span and height for the students in our class the same as the relationship between arm span and height for the students in another class?
C: Is height a useful predictor of arm span for the students in our school?

Example 4
A: Will a plant placed by the window grow taller than a plant placed away from the window?
B: Will five plants placed by the window grow taller than five plants placed away from the window?
C: How does the level of sunlight affect the growth of a plant?
Collect Data

Example 1

A: How long are the words on this page?

The length of every word on the page is determined and recorded.

B: Are the words in a chapter of a fifth grade book longer than the words in a chapter of a third grade book?

A simple random sample of words from each chapter is used.

C: Do fifth grade books use longer words than third grade books?

Other sampling designs are considered, compared and some are used. For example, rather than select words in a simple random sample, a simple random sample of pages from the book is selected and all of the words on the pages chosen are used for the sample.

Note- At each level, issues of measurement should be addressed. The length of word depends on the definition of “word.” For instance, is a number a word? Consistency of definition is important to reduce measurement variability.

Example 4

A: Will a plant placed by the window grow taller than a plant placed away from the window?

A seedling is planted in a pot which is placed on the window sill. A second seedling of the same type and size is planted in a pot which is placed away from the window sill. After six weeks the change in height for each is measured and recorded.

B: Will five plants of a particular type placed by the window grow taller than five plants of the same type placed away from the window?

Five seedlings of the same type and size are planted in a pan which is placed on the window sill. Five seedlings of the same type and size are planted in a pan which is placed away from the window sill. Random numbers are used to decide which plants go in the window. After six weeks the change in height for each seedling is measured and recorded.

C: How does the level of sunlight affect the growth of plants?

Fifteen seedlings of the same type and size are selected. Three pans are used, with five of these seedlings planted in each. Fifteen seedlings of another type are selected. Five of
these are planted in each of the three pans. The three pans are placed in locations with three different levels of light. Random numbers are used to decide which plants go in which pan. After six weeks the change in height for each seedling is measured and recorded.

Note- At each level, issues of measurement should be addressed. The method of measuring change in height must be clearly understood and applied in order to reduce measurement variability.

**Analyze Data**

*Example 2*

A: What type of music is most popular among students in our class?

A bar graph is used to display the number of students who choose each music category.

B: How do the favorite types of music compare among different classes?

For each class, a bar graph is used to display the percentage of students who choose each music category. These are scaled uniformly for comparison.

C: What type of music is most popular among students in our school?

A bar graph is used to display the percentage of students who choose each music category. Because a random sample is used, an estimate of the margin of error is given.

Note- At each level, issues of measurement should be addressed. A questionnaire will be used to gather students’ music preferences. The design and wording of the questionnaire must be carefully considered to avoid possible biases in the responses. The choice of music categories could also affect results.

*Example 3*

A: In our class, are the heights and arm spans of students approximately the same?

The difference between height and arm span is determined for each individual. An X-Y plot is constructed with X=height, Y=arm span. The line Y=X is drawn on this graph.

B: Is the relationship between arm span and height for the students in our class the same as the relationship between arm span and height for the students in another class?
For each class, an X-Y plot is constructed with X=height, Y=arm span. An "eye ball" line is drawn on each graph to describe the relationship between height and arm span. The equation of this line is determined. An elementary measure of association is determined.

C: Is height a useful predictor of arm span for the students in our school?

The least squares regression line is determined and assessed for use as a prediction model.

Note- At each level, issues of measurement should be addressed. The methods used to measure height and arm span must be clearly understood and applied in order to reduce measurement variability. For instance, do we measure height with shoes on or off?

**Interpret Results**

*Example 1*

A: How long are the words on this page?

The frequency plot of all word lengths is examined and summarized. In particular, students will note the longest and shortest word lengths, the most common lengths and least common lengths, and the length in the middle.

B: Are the words in a chapter of a fifth grade book longer than the words in a chapter of a third grade book?

The students interpret a comparison of the distribution of a sample of word lengths from the fifth grade book with the distribution of word lengths from the third grade book using box plot to represent each of these. The students also acknowledge that samples are being used which may or may not be representative of the complete chapters.

The box plot for a sample of word lengths from the fifth grade book is placed beside the box plot of the sample from the third grade book.

C: Do fifth grade books use longer words than third grade books?

The interpretation at level C includes the interpretation at level B, but also must consider generalizing from the books included in the study to a greater population of books.

*Example 4*

A: Will a plant placed by the window grow taller than a plant placed away from the window?
In this simple experiment, the interpretation is just a matter of comparing one measurement of change in size to another.

B: Will five plants placed by the window grow taller than five plants placed away from the window?

In this experiment, the student must interpret a comparison of one group of five measurements with another group.

If a difference is noted, then the student acknowledges that is likely caused by the differences in light conditions.

C: How does the level of sunlight affect the growth of a plant?

There are several comparisons of groups possible with this design. If a difference is noted, then the student acknowledges that it is likely caused by the differences in light conditions or the differences in types of plants. It is also acknowledged that the randomization used in experiment can possibly cause some of the observed differences.

**Nature of Variability**

*Variability within a group*

This is the only type considered at Level A.

In Example 1, differences among word lengths on a single page are considered; this is variability within a group of word lengths.

In Example 2, differences among how many students choose each category of music are considered; this is variability within a group of frequencies.

*Variability within a group and variability between groups*

At level B, students begin to make comparisons of groups of measurements.

In Example 1, a group of word lengths from a fifth grade book are compared to a group from a third grade book. Such a comparison not only notes differences between the two groups such as the difference between median or mean word lengths, but must also take into consideration how much word lengths differ within each group.

*Induced variability*

In Example 4, Level B, the experiment is designed to determine if there will be a difference between growth of plants in sunlight and the growth of those away from
sunlight. We want to determine if an imposed a difference on the environments will induce a difference in growth.

**Sampling variability**

In Example 1, Level B, samples of words from a chapter are used. Students observe that two different samples will produce different groups of word lengths. This is sampling variability.

**Co-variability**

Example 3, Level B or C, investigates the "statistical" relationship between height and arm span. The nature of this statistical relationship is described in terms of how the two variables "co-vary". For instance, if the height of two students differ by 2 centimeters then we would like for our model of the relationship to tell us by how much we might expect their arm spans to differ?

*Random variability from sampling*

When random selection is used, then differences between samples will be random. This random variation is what leads to the predictability of results.

In Example 2, Level C, this random variation is not only considered but it is the basis for understanding the concept of "margin or error".

**Random variability resulting from assignment to groups in experiments**

In Example 4, Level C, plants are randomly assigned to groups. Student consider how this randomization might produce differences in results, although a formal analysis is not done.

**Random variation in model fitting**

In Example 3, Level C, students assess how well a regression line will predict arm span from height. This assessment is based on the notion of random differences between actual arm spans and the arm spans predicted by the model.

**Moving Forward with Detailed Descriptions of Each Level**

As this document transitions into detailed descriptions of each level, it’s important to note that the examples selected for illustrating key concepts and the problem solving process of statistical reasoning are based on real data and real world context. The stakeholders reading the document will need to be flexible and adaptable in using these examples to fit their teaching needs and situation.
Level A

Objectives of Level A

Children are surrounded by data. They may think of data as tallying a student’s favorite object or as measurements on other students in their classroom such as arm span and number of books in their school bag.

- It is in Level A that children need to develop data sense - an understanding that data are more than just numbers. Statistics changes numbers into information.

- Students should learn that data are generated with respect to particular contexts or situations and can be used to answer questions about the context or situation.

- Students should have opportunities to generate questions about a particular context (such as their classroom) and determine what data might be collected to answer these questions.

- Students should learn how to use basic statistical tools to analyze the data and make informal or casual inferences in answering the posed questions.

- Students should develop basic ideas of probability in order to support their later use of probability in drawing inferences at levels B and C.

Statistics helps us make better decisions. It is preferable that students actually collect data but not necessary in every case. Teachers should take advantage of naturally occurring situations in which students notice a pattern about some data and begin to raise questions. For example, when taking daily attendance one morning, students might note that many students are absent. The teacher could capitalize on this opportunity to have the students formulate questions that could be answered with attendance data.

Specifically, Level A recommendations in the Investigative Process include:

1. Formulate the Question
   Teachers help pose questions
   Distinguish between statistical solution and fixed answer
   Question be in context of interest to the student

2. Collect Data to Answer the Question
   Census of the Classroom
   Understand individual to individual variability
   Simple Experiment with non-random assignment of treatment
   Understand variability due to a condition

3. Analyze the Data
   Compare individual to individual
Compare individual to a group
Introduce the idea of a distribution
Describe a distribution
Association between two variables
Tools for exploring distributions and association:
  Bar Graph
  Dotplot
  Stem-and-Leaf Plot
  Scatterplot
  Tables (using counts)
  Mean, Median, Mode, Range
  Modal Category

4. Interpretation of the Data
   Inference to the classroom
   Acknowledge results may be different in another class or group
   Recognize limitation of scope of inference to the classroom

Example 1  Choosing the Band for the End of the Year Party – Conducting a Survey

Children at Level A may be interested in the favorite type of music among students at a certain grade level. An end of the year party is being planned and there is only enough money to hire one musical group for the party. The class might investigate the question:

What type of music is most popular among students?

This question attempts to measure a characteristic in the population of the school grade children that will have the dance. The characteristic, favorite music type is a categorical variable where each child in that grade would be placed in a particular non-numerical category, based on their favorite music type. These are often called Categorical Data.

The Level A class would most likely conduct a census of the students in a particular classroom to gauge what the favorite music type might be for the whole grade. At Level A, we want students to recognize there will be individual to individual variability.

A survey of 24 students in one of the classrooms at that grade is taken with the data summarized below in the frequency count table. This frequency count table is a tabular representation of summarizing categorical data. Students might first use tally marks to summarize the measurements before finding frequencies for each category. Below is summative data for one possible classroom survey, summarizing the tally marks for each category.
<table>
<thead>
<tr>
<th>Favorite</th>
<th>Frequency or Count</th>
</tr>
</thead>
<tbody>
<tr>
<td>Country</td>
<td>8</td>
</tr>
<tr>
<td>Rap</td>
<td>12</td>
</tr>
<tr>
<td>Rock</td>
<td>4</td>
</tr>
</tbody>
</table>

A Level A student might first use a *picture graph* to represent the counts for each category. A picture graph uses a picture of some sort (such as a type of musical band) to represent each element. Thus, each child who favors a particular music type would put their cut-out of that type of band directly onto the graph the teacher has created on the board. Instead of a picture of a band, another representation such as an X or a square can be used to represent each element of the data set. A child who prefers ‘Country’ would go to the board and place a dot or X or color in a square above the column labeled “Country.” In both of these cases, there is a deliberate recording of each element, one at a time.
<table>

</tr>
</tbody>
</table>

Note that a picture graph refers to a graph where an object such as a construction paper cut-out is used to represent one element on the graph. (A cut-out of a tooth might be used to record how many teeth were lost by children in a kindergarten class each month.) The
term *pictograph* is often used to refer to a graph in which a picture or symbol is used to represent several items that belong in the same category. For example, on a graph showing the distribution of car riders, walkers, and bus riders in a class, a cut-out of a school bus might be used to represent 5 bus riders. Thus, if the class had 13 bus riders, there would be approximately 2.5 busses on the graph. This type of graph requires a basic understanding of proportional or multiplicative reasoning, and for this reason we do not advocate its use at Level A except possibly with students who are nearly ready for Level B. Similarly, circle graphs require an understanding of proportional reasoning, so we do not advocate their use at Level A except possibly at the top of level A.

A bar graph takes the student to a summative level because the data must be summarized from some other representation, such as a picture graph, a tally or frequency count table. The bar on a bar graph is drawn as a continuous rectangle reaching up to the desired number on the y-axis.

A bar graph is displayed below for the census taken of the classroom represented in the above frequency count table.

Students at Level A should recognize the *mode* as a way to describe a ‘representative’ or ‘typical’ value for the distribution.

The *mode* is the representative value that students naturally use first. The mode is most useful for categorical data. Students should understand that the *mode* is the category that contains the most data points, often referred to as the *modal category*. In our favorite
music example, rap music was preferred by more children, thus the mode or modal category of the data set is rap music. Students could use this information to help the teachers in seeking a musical group for the end of the year party that specializes in rap music.

The vertical axes on the bar graphs constructed above could be scaled in terms of the proportion or percentage of the sample size for each category. Since this involves proportional reasoning, converting frequencies to proportions (or percentages) will be developed in Level B.

Because most of the data collected at Level A will involve a census of the student’s classroom, the first stage is for students to learn to read and interpret at a simple level what the data show about their own class. Reading and interpreting comes before inference.

It is important to consider the sort of question, “What might have caused the data to look like this?”

Then, it is important for children to think about if and how their findings would “scale up” to a larger group, such as the entire grade level, the whole school, all children in the school system, all children in the state, or all people in the nation. They should note variables (such as age or geographic location) that might affect the data in the larger set. In the music example above, students might speculate that if they collected data on music preference from their teachers, the teachers might prefer a different type of music. Or what would happen if they collected music preference from middle school students in their school system? We want Level A students to begin recognizing the limitations of the scope of inference to a specific classroom.

The Simple Experiment

Another type of design for collecting data appropriate at Level A is a simple experiment which consists of taking measurements on a particular condition or group. Level A students may be interested in timing the swing of a pendulum or seeing how far a toy car runs off the end of a slope from a fixed starting position (future Pinewood Derby participants?) Data on numerical variables are obtained from situations by taking measurements such as height, length (How far can a child jump under certain conditions), or temperatures or where objects are counted (e.g., determining the number of letters in your first name, the number of pockets on clothing worn by children in the class, or the number of siblings each child has). These are often called Numerical Data. Also, measuring the same thing several times and finding a mean helps to lay the foundation for the fact that the mean has less variability as an estimate of the true value than does a single reading. This will be fully developed at Level C.

Example 2 Growing Beans – A Simple Comparative Experiment

A simple comparative experiment is like a science experiment in which children compare the results of two conditions or groups. For example, children might plant dried beans in
soil and let them sprout and then compare which one grows fastest—the one in the light or the one in the dark. The treatments or groups to be compared are the type of lighting environment—light or dark. The type of lighting environment is an example of a categorical variable. Measurements of the plants’ heights can be taken at regular intervals (e.g., every day) to collect data to answer the question of whether one lighting environment is better for growing beans. The heights collected are an example of numerical data.

An appropriate graphical representation for numerical data of one variable at Level A is a dotplot. A stem-and-leaf plot is an additional option for numerical data on one variable. Both the dotplot and stem-and-leaf plot can also be used to compare two or more similar sets of numerical data. In creating a dotplot, the $x$-axis should be labeled with a range of values that the numerical variable can assume. For example, in the bean growth experiment children might record in a dotplot the height of beans that were grown in the dark (labeled D) and in the light (labeled L) using a dot plot.

![Dotplot of Heights vs Environment](image)

It is obvious from the dotplot that the heights of the plants in the light environment tend to have higher heights than the plants in the dark environment.

Looking for clusters and gaps in the distribution helps students to identify the shape of the distribution. Students should develop a sense of why a distribution takes on a particular shape for the context of the variable being considered.
Does the distribution have one main cluster (or mound) with smaller groups of similar size on each side of the cluster? This is a symmetric distribution.

Does the distribution have one main cluster with smaller groups on each side that are not the same size? Students may classify this as ‘lopsided’ or may use the term asymmetrical. Why is the distribution taking on this shape? Using the dotplot from above, students will recognize that both groups have distributions that are ‘lopsided’ with the main cluster on the lower end of the distributions and a few values to the right of the main mound.

Another simple comparative experiment that Level A students may conduct is compare boys and girls with respect to their length of jumps. Students may measure the jumping distance for the students in their class. Once the numerical data is gathered, the children might compare the length of jumps of girls and boys using a back-to-back ordered stem-and-leaf plot.

<table>
<thead>
<tr>
<th>Girls</th>
<th>Boys</th>
</tr>
</thead>
<tbody>
<tr>
<td>10</td>
<td></td>
</tr>
<tr>
<td>9</td>

</tr>
<tr>
<td>8</td>
<td></td>
</tr>
<tr>
<td>7</td>
<td></td>
</tr>
<tr>
<td>6</td>
<td>1</td>
</tr>
<tr>
<td>5</td>
<td>2 6 9</td>
</tr>
<tr>
<td>9 7 2</td>
<td>4 1 3 5 5 5</td>
</tr>
<tr>
<td>5 5 3</td>
<td>3 1 1 2 5 6 7</td>
</tr>
<tr>
<td>3 2 1</td>
<td>2 3 4 6</td>
</tr>
<tr>
<td>9 8 7</td>
<td>6 4 4 3 2</td>
</tr>
</tbody>
</table>

Inches jumped in the standing broad jump

From the stem and leaf plot, the students can get a sense of shape (more symmetric for the boys than for the girls) with boys tending toward having longer jumps.

Making Use of Available Data

Most children love to eat hot dogs but are aware that too much sodium is not necessarily healthy. Is there as difference in the sodium content between beef hotdogs (labeled B below) and poultry hotdogs (labeled P below)? To investigate this question, students can make use of available data. Using data from the June 1986 issue of Consumer Reports magazine, parallel dotplots can be constructed.
Students will notice that the distribution of the poultry hot dogs two distinct clusters. What might explain the gap and two clusters? It could be another variable, such as the price of the poultry hog dogs with more expensive hot dogs having less sodium. It can also be observed that the beef sodium amounts are more spread out (or variable) than the poultry hot dogs. It also appears that the center of the distribution for the poultry hot dogs is higher than the center for the beef.

Describing shape connects the student to properties of geometry. As students advance to Level B, the importance of describing shape will lead to an understanding of what measures are appropriate for describing center and spread.

**Describing Center and Spread**

Students should understand that the median describes the center of a numerical data set in terms of how many data points are above and below it. Half of the data points lie above the median and half lie below it. Children can create a human graph to show how many letters are in their first name. All of the children with 2-letter names can stand in a line with all of the children having 3-letter names standing in a parallel line right next to them, etc. Once all children are assembled, the teacher can ask one child from each end of the graph to sit down, repeating this procedure until one child is left standing, representing the median. With Level A students, we advocate using an odd number of data points so that the median is clear until students have mastered understanding of a mid-point.

Students should understand the mean as a fair share at Level A. In the name length example above, the mean would be interpreted as “How long would our names be if they were all the same length?” This can be illustrated in small groups by having children take one snap cube for each letter in their name. In their small groups, have them put all of the cubes in the center of the table and redistribute them one at a time so that each child has the same number. Depending on the children’s experiences with fractions, they may say that the mean name length is 4 R. 2 or 4 1/2 or 4.5. Another example would be for the teacher to collect 8 pencils of varying lengths from children and lay them end-to-end on the chalk rail. Finding the mean will answer the question “How long would each pencil be if they were all the same length?” That is, if we could glue all of the pencils together and cut them into 8 equal sections, how long would the sections be? This can be modeled
using adding machine tape or string by tearing off a piece of tape that is the same length as all 8 pencils laid end-to-end. Then fold the tape in half three times to get eights, showing the length of one pencil out of eight pencils of equal length. Both of these demonstrations can be mapped directly onto the algorithm for finding the mean: combine all data elements (put all cubes in the middle, lay all pencils end-to-end and measure, add all elements) and share fairly (distribute the cubes, fold the tape, and divide by the number of data elements). Level A students should master the computation (by hand or using appropriate technology) of the mean so that more sophisticated definitions of the mean can be developed at Levels B and C.

Use caution when calculating a mean and median. For example, when collecting categorical data on favorite type of music, the number of children in the sample who prefer each type of music is summarized as a frequency. It is easy to confuse categorical and numerical data in this case and try to find the mean or median favorite type of music. However, one cannot use the frequency counts to describe the categorical data in terms of a mean or median because this is only appropriate for numerical data.

The mean and median are measures of location for describing the center of a numerical data set. Determining the maximum and minimum values of a numerical data set assists children in describing the position or location of the smallest and largest value in a data set. These two measures of location lead to a measure of spread for the distribution, the range.

In addition to describing the center of a data set, it is useful to know how the data are spread out. Measures of spread only make sense with numerical or measurement data.

The range is a single number that tells how far it is from the minimum element to the maximum element. In looking at the stem and leaf plot formed in Example 2 for the jumping distances, the range differs for the jumping distance of boys (range = 39 inches) and girls (range = 27 inches). Girls are more consistent in their jumping distances than boys.

Looking for an Association

Students should be able to look at the possible association of a numerical variable and a categorical variable by comparing dotplots of a numerical variable disaggregated by a categorical variable. For example, using the parallel dot plots showing the growth habits of beans in the light and dark, students should look for similarities within each category and differences between the categories. As mentioned earlier, students should readily recognize from the dot plot that the beans grown in the light environment have grown taller overall and reason that it is best for beans to have a light environment. Measures of center and spread can also be compared. For example, students could calculate or make a visual estimate of the mean height of the beans grown in the light and the beans grown in the dark to substantiate their claim that light conditions are better for beans. They might also note that the range for plants grown in the dark is 4 and for plants grown in the light is 5. Putting that information together with the mean should enable students to further
solidify their conclusions about the advantages of grown beans in the light. Considering the hot dog data, general impressions from the dot plots are that there is more variation in the sodium content for beef hot dogs. For beef hot dogs the sodium contents are between 250 and 650, while for poultry hot dogs all are between 350 and 600. Neither the centers nor the shapes for the distributions are obvious from the dot plots. It is interesting to note the two apparent clusters of data for poultry hot dogs. Nine of the 17 poultry hot dogs have sodium content between 350 and 450 mg, while 8 of the 17 poultry hot dogs have sodium content between 500 and 650 mg. A possible explanation for this division is that some poultry hot dogs are made from chicken, while others are made from turkey.

Example 3 Purchasing Sweatsuits – The Role of Height and Armspan?

What about the association between two numerical variables? Parent–teacher organizations at elementary schools have as a popular fund raiser ‘spirit wear’ such as sweatshirts and sweatpants with the school name and mascot. The organizers need to have some guidelines on how to order sizes. Should they offer the shirt and pants separately or offer the sweatshirt and sweatpants as one outfit? Are the heights and arm spans of elementary closely related or due to growing patterns of children, are they different? Thus, some useful questions to answer are:

Is height a useful predictor of arm span?

How strong is the association between height and arm span?

A scatterplot can be used to graphically represent data when values of two numerical variables are obtained from the same individual or object. Can we use arm span to predict a person’s height? Students can measure each other’s arm spans and heights, and then construct a scatterplot to look for a relationship between these two numerical variables. Data on height and arm span are measured in centimeters for 26 students. [Note that for illustrative purposes, the data presented below if for college students.]
With the use of a scatterplot, level A students can visually *look for trends and pattern*. For example, in the arm span vs. height scatterplot above, students should be able to identify the consistent relationship between the two variables: as one gets larger, so does the other. Based on this sample, the organizers might feel comfortable in ordering some complete outfits of sweatshirt and sweatpants based on sizes. However, some students may need to order the sweatshirt and sweatpants separately based on sizes. Another important question the organizers will need to ask is whether this sample is representative of all the students in the school? How was the sample taken?

Students at Level A can also use a scatterplot to graphically look at the relationship of a numerical variable over time, referred to as a *time plot*.

For example, children might chart the outside temperature at various times during the day by recording the values themselves or by using data from a newspaper or the internet.
When the student advances to Level B, these trends and patterns will be quantified with measures of association.

**Understanding variability**

Students should explore possible reasons that data look the way they do and differentiate between variation and error. For example, in graphing the colors of candies in a small packet, children might expect the colors to be evenly distributed (or they may know from prior experience that they are not). Children could speculate about why certain colors appear more or less frequently due to variation (e.g., cost of dyes, market research on people’s preferences, etc.). Children could also identify possible places where errors could have occurred in their handling of the data/candies (e.g., dropped candies, candies stuck in bag, eaten candies, candies given away to others, colors not recorded because they don’t match personal preference, miscounting). Teachers should capitalize on naturally-occurring “errors” that happen when collecting data in the classroom and help students speculate about the impact of these errors on the final results. For example, when asking students to vote for their favorite food, it is common for students to vote twice, to forget to vote, to record their vote in the wrong spot, to misunderstand what is being asked, to change their minds, or to want to vote for an option that is not listed. Counting errors are also common among young children and can lead to incorrect tallies of data points in categories. Teachers can help students think about how these events might affect the final outcome if only one person did this, if several people did it, or if many people did it. Students can generate additional examples of ways that errors might occur in a particular data-gathering situation.

The notions of error and variability should be used to explain the outliers, clusters, and gaps that students observe in the graphical representations of the data. An understanding
of error versus natural or expected variability will help students to interpret whether an outlier is usual (to be expected) or is the outlier unusual (could it be a recording error?)

At level A, it is imperative that students begin to understand this concept of variability. As students move from Level A to Level B, then Level C, it is important to always keep at the forefront that understanding variability is the essence of developing data sense.

**The role of probability**

Level A students need to develop basic ideas of probability in order to support their later use of probability in drawing inferences at levels B and C.

At level A, students should understand that probability is a measure of the chance that something will happen. It is a measure of certainty or uncertainty. Events should be seen as lying on a continuum from impossible to certain, with less likely, equally likely, and more likely lying in between. Students learn to informally assign numbers to the likelihood that something will occur. An example of assigning numbers on a number line is given below.

<table>
<thead>
<tr>
<th>0</th>
<th>¼</th>
<th>1/2</th>
<th>¾</th>
<th>1</th>
</tr>
</thead>
<tbody>
<tr>
<td>Impossible</td>
<td>Unlikely</td>
<td>Equally likely</td>
<td>Likely</td>
<td>Certain</td>
</tr>
<tr>
<td>Or less likely</td>
<td>to occur and not occur</td>
<td>or more likely</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Student should have experiences finding probabilities using empirical data. Through experimentation (or simulation), students should develop an explicit understanding of the notion that the more times you repeat an experiment, the closer the results will be to the expected mathematical model. At Level A we are only considering simple models based on equally likely outcomes or, at the most, something based on this such as the sum of the faces on two number cubes. For example, very young children can state that a penny should land on heads half the time and on tails half of the time when flipped. The student has given the expected model and probability for tossing a head or tail, assuming that the coin is ‘fair’. However, if a child flips a penny 10 times to obtain empirical data, it is quite possible that s/he will not get 5 heads and 5 tails. If all children in the class flip a penny 10 times and the results are aggregated across the class, we would expect to see that the results will begin stabilizing to the expected probabilities of 50% heads and 50% tails. This is known as the Law of Large Numbers. Thus, at Level A, probability experiments should focus on obtaining empirical data to develop relative frequency interpretations that children can easily translate to models with known and understandable ‘mathematical’ probabilities. The classic flipping coins, spinning simple spinners and tossing a number cube are reliable tools to use in helping level A students develop an understanding of probability. The concept of relative frequency
interpretations will be important at Level B when the student works with proportional reasoning – going from counts or frequencies to proportions or percentages.

As students work with empirical data, such as flipping a coin, they can develop an understanding for the concept of *randomness*. They will see that when flipping a coin 10 times, although we would expect 5 heads and 5 tails, the actual results will vary from one student to the next. They will also see that if a head results that doesn’t mean that the next flip will result in a tail. With a random process, there is always uncertainty as to how the coin will land from one toss to the next. However, at level A, students can begin to develop the notion that although we have uncertainty and variability in our results, by examining what happens to the random process in the *long run*, we can quantify the uncertainty and variability with probabilities – giving a predictive number for the likelihood of an outcome in the long run. At Level B, students will develop the concept of the simple random sample and will see the role that probability plays with randomness.

**Conclusion**

If students become comfortable with the ideas and concepts described above, they will be prepared to further develop and enhance their understanding of the key concepts for data sense at level B.

It is also important to recognize that helping students develop data sense at Level A allows mathematics instruction to be driven by data. The traditional mathematics strands of algebra, functions, geometry, and measurement can all be developed with the use of data. Making sense of data should be an integrated part of the mathematics curriculum starting in kindergarten.
Level B

Objectives of Level B

Instruction at Level B should build on the statistical base developed at Level A and set the stage for statistics at Level C. Instructional activities at Level B should continue to emphasize the four main components in the investigative process, and should have the spirit of genuine statistical practice. Students who complete Level B should see statistical reasoning as a process for solving problems through data and quantitative reasoning. At Level B:

Students become more aware of the statistical question distinction (a question with an answer based on data that vary versus a question with a deterministic answer).

Students make decisions about what variables to measure and how to measure them in order to address the question posed.

Students use and expand the graphical, tabular and numerical summaries introduced at Level A to investigate more sophisticated problems.

Students develop a basic understanding the role of probability in random selection when selecting a sample and random assignment when conducting an experiment.

Students investigate problems with more emphasis placed on possible associations among two or more variables and understand how a more sophisticated collection of graphical, tabular and numerical summaries is used to address these questions.

Students recognize ways that statistics is used or misused in their world.

Specifically, Level B recommendations in the Investigative Process include:

1. **Formulate Questions**
   - Students begin to pose their own questions
   - Students address questions involving a group larger than their classroom and begin to recognize the distinction between a population, a census, and a sample

2. **Collect Data**
   - Students conduct censuses of two or more classrooms
   - Students conduct non-random sample surveys and begin to use random selection
   - Students conduct comparative experiments and begin to use random allocation

3. **Analyze Data**
Students expand understanding of a data distribution
Students quantify variability within a group
Students compare two or more distributions in displays and with summary measures
Students use expanded tools for summarizing and comparing distributions including:
  - Histograms
  - The IQR (Inter-Quartile Range) and MAD (Mean Absolute Deviation)
  - Five-Number Summaries and Boxplots
Students acknowledge sampling error
Students quantify the strength of association between two variables, develop simple models for association between two numeric variables, and use expanded tools for exploring association including:
  - Contingency Tables for two categorical variables
  - Time Series
  - The QCR (Quadrant Count Ratio) as a measure of strength of association
  - Simple lines for modeling association between two numeric variables

4. **Interpret Results**
Students describe differences between two or more groups with respect to center, spread, and shape
Students acknowledge that a sample may not be representative of larger population
Students understand basic interpretations of measures of the association and models for association
Students become aware of the distinction between an observational study and a designed experiment
Students become aware of the distinction between “association” and “cause and effect”
Students recognize sampling variability in summary measures

**Example 1, Level A Revisited: Choosing a Band for the School Dance**

Many of the graphical, tabular and numerical summaries introduced at Level A can be used and expanded to investigate more sophisticated problems at Level B. Let’s revisit planning for the school dance problem introduced in Level A where a Level A class investigated the question:

**What type of music is most popular among students in our class?**

by conducting a census of the class. That is, the class was considered to be the entire population and data were collected on every member of the population. A similar investigation at Level B would include recognition that one class may not be representative of the opinions of all students at their school, and Level B students might want to compare the opinions of their class with other classes from their school. A Level B class might investigate the questions:
What type of music is most popular among students at our school?

How do the favorite types of music compare between different classes?

Since class sizes may be different, in order to make comparisons, results should be summarized with relative frequencies or percentages. Percentages are useful in that they allow us to think of having comparable results for groups of size 100. Level B students will see more emphasis in proportional reasoning throughout the mathematics curriculum, and they should be comfortable summarizing and interpreting data in terms of percentages or fractions.

The results from two classes are summarized in the table below using both frequency counts and relative frequency percentages.

| Favorite | Class 1 |  |  | Class 2 |  |  |
|----------|---------|  |  |---------|  |  |
|          | Frequency | Relative Frequency |  | Frequency | Relative Frequency |  |
| Country  | 8       | 33%           |  | Country  | 5       | 17%           |
| Rap      | 12      | 50%           |  | Rap      | 11      | 37%           |
| Rock     | 4       | 17%           |  | Rock     | 14      | 47%           |
|          | 24      | 100%          |  |          | 30      | 101%          |

The bar graph below compares the percentage for favorite music between the two classes.
Students at Level B should begin to recognize that there is not only variability from one individual to another within a group, but that there is variability in results from one group to another. This second type of variability is illustrated by the fact that in Class 1 the most popular music is rap music while in Class 2 it is rock music. That is, the mode for Class 1 is rap music, while the mode for Class 2 is rock music.

The results from the two samples might be combined in order to have a larger sample of the entire school. The combined results indicate that rap music was the favorite type of music for 43% of the students, rock music was preferred by 33%, while only 24% of the students selected country music as their favorite. Level B students should recognize that although this is a larger sample, it may not be representative of the entire population (all students at their school). In statistics, randomness and probability are incorporated into the sample selection procedure in order to provide a method that is fair and to improve the chances of selecting a representative sample. For example, if the class decides to select what is called a simple random sample of 54 students, then each possible sample of 54 students has the same probability of being selected. This application of probability illustrates one of the roles of probability in statistics. Although Level B students may not actually employ a random selection procedure when collecting data, issues related to obtaining representative samples should be discussed at Level B.

**Connecting Two Categorical Variables**

Since rap was the most popular music for the combined two classes, the students might argue for a rap band for the dance. However, more than half of those surveyed preferred either rock or country music. Will these students be unhappy if a rap band is chosen? Not necessarily since many students who like rock music may also like rap music as well. To investigate this problem, students might explore two additional questions.

*Do students who like rock music tend to like or dislike rap music?*

*Do students who like country music tend to like or dislike rap music?*

To address these questions, the survey should ask students not only their favorite type of music, but also whether or not they like rap, rock, and country music.

The Two-Way Frequency Table (or Contingency Table) below provides a way to investigate possible connections between two categorical variables.

<table>
<thead>
<tr>
<th></th>
<th>Like Rap Music?</th>
<th></th>
<th>Row Totals</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Yes</td>
<td>No</td>
<td></td>
</tr>
<tr>
<td>Like Rock Music?</td>
<td>27</td>
<td>6</td>
<td>33</td>
</tr>
<tr>
<td>Column Totals</td>
<td>31</td>
<td>23</td>
<td>54</td>
</tr>
</tbody>
</table>
According to these results, of the 33 students who liked rock music, 27 also liked rap music. That is, 82% (27/33) of the students who like rock music also like rap music. This indicates that students who like rock music tend to like rap music as well. A similar analysis could be performed to determine if students who like country tend to like or dislike rap music. Once again, notice the use of proportional reasoning in interpreting these results.

**Questionnaires and Their Difficulties**

At level B, students should begin to learn about surveys and the many pitfalls to avoid when designing and conducting a survey. One issue involves the wording of questions.

Questions must be unambiguous and easy to understand. For example, the questions:

*Are you against the school implementing a non-door policy on bathroom stalls?*

is worded in a confusing way. An alternative way to pose this question is:

*The school is considering implementing a non-door policy on bathroom stalls. What is your opinion regarding this policy?*

*Strongly Oppose  Oppose  No Opinion  Support  Strongly Support*

Questions should avoid leading the respondent to an answer. For example, the question

*Since our football team hasn’t had a winning season in 20 years and is costing the school money rather than generating funds, do you feel we should concentrate more on another sport such as soccer or basketball?*

is worded a way that is biased against the football team.

The response to question with coded responses should include all possible answers and should not overlap. For example, if the responses to question

*How much time do you spend studying at home on a typical night?*

then the responses:

*none  up to 1 hour  more than 1 hour*

confuses a student who spends 1 hour a night studying.

There are many other issues concerning question formulation and conducting sample surveys. One issue that should be discussed at Level B involves how the interviewer asks the questions as well as how accurately the responses are recorded. It is important for
students to realize that the conclusions from their study depend on the accuracy of their data.

Measure of Center – The Mean as Balance Point

Another idea developed at Level A that can be expanded at Level B is the mean for a collection of numeric data. At Level A the mean is interpreted as the “fair share” value for data. That is, the mean is the value you would get if all the data are combined and then redistributed evenly so that each value is the same. Another interpretation of the mean is that it is the balance point of the corresponding data distribution. Following is an outline of an activity that illustrates the notion of the mean as a balance point.

Nine students were asked: “How many pets do you have?”
The resulting data are: 1, 3, 4, 4, 4, 5, 7, 8, 9. These data are summarized in the dot plot below.
Note that in the actual activity, stick-on notes are used as “dots” instead of X’s.

If the pets are combined into one group there are a total of 45 pets. If the pets are redistributed evenly among the 9 students, then each student would get 5 pets. That is, the mean number of pets is 5. The dot plot representing the result that all 9 students have exactly 5 pets is shown below:

It is hopefully obvious that if a pivot is placed at the value 5 then the horizontal axis will “balance” at this pivot point. That is, the “balance point” for the horizontal axis for this dot plot is 5. What is the balance point for the dot plot displaying the original data?

We begin by noting what happens if one of the dots over 5 is removed and placed over the value 7 as shown below.
Clearly, if the pivot remains at 5, the horizontal axis will tilt right. What can be done to the remaining dots over 5 to “re-balance” the horizontal axis at the pivot point? Since 7 is 2 above 5, one solution is to move a dot 2 below 5 to 3 as shown below:

Clearly, the horizontal axis is now re-balanced at the pivot point. Is this the only way to re-balance the axis at 5? Another way to re-balance the axis at the pivot point would be to move two dots from 5 to 4 as shown below:

The horizontal axis is now re-balanced at the pivot point. That is, the “balance point” for the horizontal axis for this dot plot is 5. Replacing each “X” (dot) in this plot with the distance between the value and 5, we have:
Notice that the total distance for the two values below the 5 (the two 4’s) is the same as the total distance for the one value above the 5 (the 7). For this reason, the balance point of the horizontal axis is 5. Replacing each value in the dot plot of the original data by its distance from 5 yields the following plot.

![Dot plot](image)

Notice that the total distance for the values below 5 is 9, the same as the total distance for the values above 5. For this reason, the mean (5) is the balance point of the horizontal axis.

Both the mean and median are often referred to as measures of center. At Level A the median was also introduced as the quantity that has the same number of data values on each side of it in the ordered data. This sameness of each side is the reason the median is a measure of center. The previous activity demonstrates that the total distance for the values below the mean is the same as the total distance for the values above the mean and illustrates why the mean is also considered to be a measure of center.

**A Measure of Spread – The Mean Absolute Deviation**

Statistics is concerned with variability in data. One important idea is to quantify how much variability exists in a collection of numerical data. Quantities that measure the degree of variability in data are called measures of spread. At Level A students are introduced to the Range as a measure of spread in numeric data. At Level B students should be introduced to the idea of comparing data values to a central value such as the mean or the median, and quantifying how different the data are from this central value.

In the number of pets example, how different are the original data values from the mean? One way to measure the degree of variability from the mean is to determine the total distance for all values from the mean. Using the final dot plot from the previous example, the total distance the nine data values are from the mean of 5 pets is 18 pets. The magnitude of this quantity depends on several factors, including the number of measurements. To adjust for the number of measurements, the total distance from the mean is divided by the number of measurements. The resulting quantity is called the Mean Absolute Deviation or MAD. The MAD is the average distance of all the data from the mean. That is,

\[
\text{MAD} = \frac{\text{Total Distance for all Values from the Mean}}{\text{Number of Data Values}}
\]
The MAD for the data on number of pets from the previous activity is:

\[
\text{MAD} = \frac{18}{9} = 2
\]

The MAD indicates that the actual number of pets for the 9 students differ from the mean of 5 pets on average by 2 pets.

The MAD is an indicator of spread based on all the data and provides a measure of average variation in the data from the mean. The MAD also serves as a precursor to the standard deviation developed at Level C.

**Representing Data Distributions – The Frequency Table, Histogram**

At Level B, students should develop additional tabular and graphical devices for representing data distributions for numeric variables. Several of these can build upon representations developed at Level A. For example, students at Level B might explore the problem of placing an order for hats. To prepare an order, one needs to know which hat sizes are most common and which occur least often. To obtain information about hat sizes it is necessary to measure head circumferences. In planning an order for adults, students might collect preliminary data on the head circumferences of their parents, guardians, or other adults. Such data would be the result of a non-random sample. The data summarized in the following stem and leaf plot are head circumferences measured in millimeters for a sample of 55 adults.

\[
\begin{array}{c}
51 \mid 3 \\
52 \mid 5 \\
53 \mid 133455 \\
54 \mid 2334699 \\
55 \mid 12222345 \\
56 \mid 0133355588 \\
57 \mid 113477 \\
58 \mid 02334458 \\
59 \mid 1558 \\
60 \mid 13 \\
61 \mid 28 \\
\end{array}
\]

Based on the stem and leaf plot, some head sizes do appear to be more common than others. Head circumferences in the 560’s are most common. Head circumferences fall off in somewhat of a symmetric manner on both sides of the 560’s with very few smaller than 530 mm or larger than 600 mm.

In practice, a decision of how many hats to order would be based on a much larger sample, possibly hundreds or even thousands of adults. If a larger sample were available, a stem and leaf plot would not be a practical device for summarizing the data distribution. An alternative to the stem and leaf display is to form a distribution based on groups or intervals of data. This method can be illustrated through a smaller data set such as the 55 head circumferences but is applicable for larger sets as well. The *grouped frequency* and
grouped relative frequency distributions and the relative frequency histogram that correspond to the above stem-and-leaf plot are:

<table>
<thead>
<tr>
<th>Limits on Head Interval of Head Circumferences</th>
<th>Frequency</th>
<th>Relative Frequency (%)</th>
</tr>
</thead>
<tbody>
<tr>
<td>51 510 - 519</td>
<td>1</td>
<td>1.8</td>
</tr>
<tr>
<td>52 520 - 529</td>
<td>1</td>
<td>1.8</td>
</tr>
<tr>
<td>53 530 - 539</td>
<td>6</td>
<td>10.9</td>
</tr>
<tr>
<td>54 540 - 549</td>
<td>7</td>
<td>12.7</td>
</tr>
<tr>
<td>55 550 - 559</td>
<td>8</td>
<td>14.5</td>
</tr>
<tr>
<td>56 560 - 569</td>
<td>10</td>
<td>18.2</td>
</tr>
<tr>
<td>57 570 - 579</td>
<td>6</td>
<td>10.9</td>
</tr>
<tr>
<td>58 580 - 589</td>
<td>8</td>
<td>14.5</td>
</tr>
<tr>
<td>59 590 - 599</td>
<td>4</td>
<td>7.3</td>
</tr>
<tr>
<td>60 600 - 609</td>
<td>2</td>
<td>3.6</td>
</tr>
<tr>
<td>61 610 - 619</td>
<td>2</td>
<td>3.6</td>
</tr>
<tr>
<td><strong>TOTAL</strong></td>
<td><strong>55</strong></td>
<td><strong>99.8</strong></td>
</tr>
</tbody>
</table>

If the hat manufacturer requires that orders be in multiples of 250 hats then, based on the above results, how many hats of each size should be ordered? Using the relative frequency distribution, the number of each size to order for an order of 250 hats would be:

<table>
<thead>
<tr>
<th>Hat Size</th>
<th>Number to Order</th>
</tr>
</thead>
<tbody>
<tr>
<td>51</td>
<td>5</td>
</tr>
<tr>
<td>52</td>
<td>5</td>
</tr>
<tr>
<td>53</td>
<td>27</td>
</tr>
<tr>
<td>54</td>
<td>32</td>
</tr>
</tbody>
</table>
Once again, notice how students at Level B would utilize proportional reasoning in determining the number to order of each size.

**Comparing Distributions – The Boxplot**

Problems that require comparing distributions between two or more groups are common in statistics. For example, at Level A students compared the amount of sodium between “beef” and “poultry” hotdogs by examining parallel dotplots. At Level B more sophisticated representations should be developed for comparing distributions. One of the most useful graphical devices for comparing distributions of numeric data is the boxplot. The boxplot (also called a box-and-whiskers plot) is a graph based on a division of the ordered data into four groups with the same number of data values in each group (approximately one-fourth). The four groups are determined from the Five-Number Summary (the minimum data value, the first quartile, the median, the third quartile, and the maximum data value). The Five-Number Summaries and comparative box plots for the data on sodium content for beef (labeled B) and poultry (labeled P) hot dogs introduced in Level A are given below.

<table>
<thead>
<tr>
<th></th>
<th>Beef Hot Dogs (n=20)</th>
<th>Poultry Hot Dogs (n = 17)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Minimum</td>
<td>253</td>
<td>357</td>
</tr>
<tr>
<td>First Quartile</td>
<td>320.5</td>
<td>379</td>
</tr>
<tr>
<td>Median</td>
<td>380.5</td>
<td>430</td>
</tr>
<tr>
<td>Third Quartile</td>
<td>478</td>
<td>535</td>
</tr>
<tr>
<td>Maximum</td>
<td>645</td>
<td>588</td>
</tr>
</tbody>
</table>

Interpreting results based on a boxplot analysis requires comparisons based on global characteristics of each distribution (center, spread, and shape). For example, the median sodium content for poultry hot dogs is 430 mg, almost 50 mg more than the median.
sodium content for beef hot dogs. The medians indicate that a central value for poultry hot dogs typically has more sodium than a central value for beef hot dogs. The range for the beef hot dogs is 392 mg versus 231 mg for the poultry hot dogs. The ranges indicate that overall, there is more spread (variation) in beef hot dogs compared to poultry hot dogs. Another measure of spread that should be introduced at Level B is the interquartile range or IQR. The IQR is the difference between the third and first quartiles and indicates the range of the middle 50% of data. The IQR’s are 157.5 mg for beef and 156 mg for poultry hot dogs. The IQR’s suggest that the spread within the middle half of data for beef hot dogs is similar to spread within the middle half of data for poultry hot dogs. The box plots also suggest that each distribution is slightly skewed right. That is, each distribution appears to have somewhat more variation in the upper half. Finally, it is interesting to note that more than 25% of beef hot dogs have less sodium than all poultry hot dogs. On the other hand, the highest sodium levels are for beef hot dogs.

Note that there are several variations of boxplots. At Level C a boxplot analysis might include an analysis for outliers (values that are extremely large or small when compared to the variation in the majority of the data). If outliers are identified, these are often detached from the “whiskers” of the plot. Outlier analysis is not appropriate at Level B and whiskers are attached to the minimum and maximum data values.

**Measuring the Strength of Association between Two Quantitative Variables**

At Level B, more sophisticated data representations should be developed for the investigation of problems that involve the study of the relationship between two numeric variables. At Level A, the problem of packaging sweatsuits (shirt and pants together or separate) was examined through a study of the relationship between height and arm span. There are several statistical questions related to this problem that can be addressed at Level B which require a more in-depth analysis of the height-arm span data. For example,

*How strong is the association between height and arm span?*

*Is height a useful predictor of arm span?*

Following are data on height and arm span measured in centimeters for 26 students. For convenience, the data on height have been ordered.

<table>
<thead>
<tr>
<th>Height</th>
<th>Arm Span</th>
<th>Height</th>
<th>Arm Span</th>
</tr>
</thead>
<tbody>
<tr>
<td>155</td>
<td>151</td>
<td>173</td>
<td>170</td>
</tr>
<tr>
<td>162</td>
<td>162</td>
<td>175</td>
<td>166</td>
</tr>
<tr>
<td>162</td>
<td>161</td>
<td>176</td>
<td>172</td>
</tr>
<tr>
<td>163</td>
<td>172</td>
<td>176</td>
<td>172</td>
</tr>
<tr>
<td>164</td>
<td>167</td>
<td>178</td>
<td>173</td>
</tr>
<tr>
<td>164</td>
<td>155</td>
<td>178</td>
<td>166</td>
</tr>
<tr>
<td>165</td>
<td>164</td>
<td>181</td>
<td>183</td>
</tr>
<tr>
<td>165</td>
<td>164</td>
<td>183</td>
<td>181</td>
</tr>
<tr>
<td>166</td>
<td>167</td>
<td>183</td>
<td>179</td>
</tr>
</tbody>
</table>
The height and arm span data (measured in centimeters) for 26 students are displayed in the following scatterplot. The scatterplot suggests a fairly strong increasing relationship between height and arm span, and the relationship between height and arm span appears to be quite linear.

Measuring the strength of association between two variables is an important statistical concept that should be introduced at Level B. The scatterplot below for the Height/Arm Span data includes a vertical line drawn through the mean height and a horizontal line drawn through the mean arm span.
The two lines divide the scatter plot into four regions (or quadrants). The upper right region (Quadrant 1) contains points that correspond to individuals with above average height and above average arm span. The upper left region (Quadrant 2) contains points that correspond to individuals with below average height and above average arm span. The lower left region (Quadrant 3) contains points that correspond to individuals with below average height and below average arm span. The lower right region (Quadrant 4) contains points that correspond to individuals with above average height and below average arm span.

Notice that most points in the scatter plot are in either Quadrant 1 or Quadrant 3. That is, most people with above average height also have above average arm span (Quadrant 1) and most people with below average height also have below average arm span. Two people have above below heights with above average arm span (Quadrant 2) and one person has above average height with below average arm span (Quadrant 4). These results indicate that there is a positive association between the variables height and arm span. Generally stated, two numeric variables are positively associated when above average values of one variable tend to occur with above average values of the other and when below average values of one variable tend to occur with below average values of the other. Negative association between two numeric variables can be stated in a similar way.

A correlation coefficient is a quantity that measures the direction and strength of an association between two variables. Note that in the previous example, points in Quadrants
1 and 3 contribute to the positive association between height and arm span, and there are a total of 23 points in these two quadrants. Points in Quadrants 2 and 4 contribute to the negative association between height and arm span, and there are a total of 3 points in these two quadrants. One correlation coefficient between height and arm span is given by the QCR (Quadrant Count Ratio):

\[
\text{QCR} = \frac{23 - 3}{26} = .77
\]

A QCR of .77 indicates that there is a fairly strong positive association between the two variables height and arm span. This indicates that a person’s height is a useful predictor of his/her arm span.

In general, the QCR is defined as:

\[
\frac{[\text{Number of Points in Quadrants 1& 3} - \text{Number of Points in Quadrants 2& 4}]}{\text{Number of Points in all Four Quadrants}}
\]

The QCR has the following properties:

- The QCR is unitless
- The QCR is always between –1 and +1 inclusive

The QCR is a measure of the strength of association based only on the number of points in each quadrant and, consequently, has its shortcomings. At Level C the shortcomings of the QCR can be addressed and used as foundation for developing Pearson’s correlation coefficient.

**Modeling Linear Association**

The height – arm span data was collected at Level A in order to study the problem of packaging sweatsuits. Should the shirt and pants be packaged separately or together? A QCR of .77 suggests a fairly strong positive association between height and arm span, which indicates that height is a useful predictor of arm span and that the shirt and pants could be packaged together. If packaged together, how can person decide which size sweatsuit to buy? Certainly, the pant-size of a sweatsuit depends on a person’s height and the shirt-size depends on a person’s arm span. Since many people know their height, but may not know their arm span, can height be used to help people decide which size sweatsuit they wear? Specifically,

*Can the relationship between height and arm span be described using a linear function?*

The study of linear relationships will be introduced in other areas of the mathematics curriculum to students at Level B. The degree to which these ideas have been developed will determine how we might proceed at this point. For example, if students have not yet...
been introduced to the equation of a line, then they might simply draw a line through the “center of the data” as shown below:

\[
\text{ArmSpan} = 1.000 \times \text{Height} - 3.1
\]

This line can be used to predict a person’s arm span if his or her height is known. For example, to predict the arm span for person who is 170 cm tall, we would draw a vertical line up from the X-axis at Height = 170. At the point this vertical line intersects the line, draw a horizontal line to the Y-axis. The value where this horizontal line intersects the Y-axis is the predicted arm span. Based on the graph above, it appears that we would predict an arm span of approximately 166 cm for person who is 170 cm tall.

If students are familiar with the equation for a line and know how to determine the equation from two points, then they might determine the Mean – Mean line, which is determined as follows. Order the data according to the X-coordinates and divide the data into two “halves” based on this ordering. In the case that you have an odd number of measurements, remove the middle point from the analysis. Determine the means for the X-coordinates and Y-coordinates in each half and determine the equation of the line that passes through these two points. Using the previous data:

<table>
<thead>
<tr>
<th>Lower Half (13 Points)</th>
<th>Upper Half (13 Points)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mean Height = 164.8</td>
<td>Mean Height = 180.2</td>
</tr>
<tr>
<td>Mean Arm Span = 163.4</td>
<td>Mean Arm Span = 175.2</td>
</tr>
</tbody>
</table>
The equation of the line that goes through the points (164.8, 163.4) and (180.2, 175.2) is: Predicted Arm Span ≈ 37.1 + .766(Height). This equation can be used to more accurately predict a person’s height than an eye-ball line. For example, if a person is 170 cm tall, then we would predict his/her height to be approximately: 37.1 + .766(170) = 167.3 cm.

The Role of Randomness

In statistics, we will often want to extend the results beyond the particular group studied to a larger group, the population. We are trying to gain information about the population by examining a portion of the population, called a sample. Such generalizations are only valid, however, if the data are representative of that larger group. A representative sample is one in which the relevant characteristics of the sample members are generally the same as the characteristics of the population. Improper or biased sample selection tends to systematically favor certain outcomes and can produce misleading results and erroneous conclusions.

Random sampling is a way to remove bias in sample selection and tends to produce representative samples. Random sampling attempts to reduce bias in sample selection by being fair to each member of the population. At Level B, students should experience the consequences of non-random selection and develop a basic understanding of the principles involved in random selection procedures. Following is a description of an activity that allows students to compare sample results that are based on personal (non-random) selection versus sample results that are based on random selection.

Consider the 80 circles on the next page. What is the average diameter for these 80 circles? Each student should take about 15 seconds and select five circles that he/she thinks best represents the size of all 80 circles. After selecting their sample, each student should find the average diameter for the circles in her/his personal sample. Note that the diameter for the small circles is 1 cm, for the medium sized circles is 2 cm, and for the large circles is 3 cm.

Next, each student should number the circles from 1 to 80 and use a table of random digits to select a random sample of size 5. Each student should find the average diameter for the circles in her/his random sample. The sample mean diameters for the entire class results can be summarized for the two selection procedures with back-to-back stem and leaf plots.

How do the means for the two sample selection procedures compare with the true mean diameter of 1.25 cm? Personal selection will tend to yield sample means that are generally larger than 1.25. That is, personal selection tends to be biased with a systematic favoring toward the larger circles and an overestimation of the population mean. Random selection tends to produce sample means that both underestimate and overestimate the population mean, but on the average, yield the population mean. That is, random selection tends to be unbiased.
In the previous example, the fact that the sample means vary from one sample to another illustrates an idea that was introduced earlier in the favorite music type survey. This is the notion that results vary from one sample to another. Imposing randomness into the sampling procedure allows us to use probability to predict the long-run behavior in the variability in the sample means from repeated sampling. The variation in results from repeated sampling is described through what is called the sampling distribution. Sampling distributions will be explored in depth at Level C.
Eighty Circles
Comparative Experiments

Another important statistical idea that should be introduced at Level B is that of comparative experimental studies. Comparative experimental studies involve comparisons of the effects of two or more treatments. At Level B, studies comparing two treatments are adequate. For example, we might want to study the effects of listening to rock music on one’s ability to memorize. Before undertaking a study such as this, it is important that students have the opportunity to identify and, as much as possible, to adjust for as many potential extraneous sources that may interfere with the results. To address these issues, the class needs to develop a design strategy for collecting appropriate data.

One simple experiment would be to randomly divide the class into two equal sized (or near equal sized) groups. Random assignment provides a fair way to assign students to each group that tends to average out differences in student ability and other characteristics that might affect the result. For example suppose a class has 28 students. The 28 students are randomly assigned into one of two groups of fourteen. One way to accomplish this is to place 28 pieces of paper in a box –14 labeled “M” and 14 labeled “S.” Shake the box well and have each student randomly choose a piece of paper. The 14 M’s will listen to music and the 14 S’s will have silence.

Each student will be shown a list of words. Rules for how long students have to study the words and how long they have to reproduce the words must be determined. For example, students may have two minutes to study the words, a one-minute pause, and then two minutes to reproduce (write down) as many words as possible. The number of words remembered under each condition (listening to music or silence) is the variable of interest.

The Five-Number Summaries and comparative box plots for a hypothetical set of data are shown below. These results suggest that students generally memorize fewer words when listening to music compared to when there is silence. With the exception of the maximum value in the Music Group (which is classified as an outlier), all summary measures for the Music Group (labeled M) are lower than the corresponding summary measures for the Silence Group (labeled S). Without the outlier, the degree of variation in the scores appears to be similar for both groups, and both distributions appear to be reasonably symmetric.

Another important statistical idea that should be introduced at Level B is that of time series. Problems that explore trends in data over time are quite common. For example, the population of the United States and the world continue to grow, and there are several factors that affect the size of a population such as the number of births and the number of deaths per year. One question we ask is:

*How has the number of live births changed over the past 30 years?*

The United States Census Bureau publishes vital statistics in its annual Statistical Abstract of the United States. The data below represent the number of live births per year for residents of the United States since 1970. Note that in 1970, the value 3,731 represents 3,731,000 live births.

The scatterplot below shows the number of live births over time. This graph indicates that:

- from 1970 to 1975, the number of live births generally declined,
- from 1976 to 1990, the number of live births generally increased,
- from 1991 to 1997, the number of live births generally declined,
- and it appears that the number of live births may have started to increase since 1997.

**Summary of Level B**

Understanding the statistical concepts of Level B enables a student to begin to appreciate that data analysis is an investigative process consisting of formulating their own questions, collecting data through various sources (censuses, non-random and random sample surveys, and comparative experiments with random allocation), analyzing data through graphs and simple summary measures, and interpreting results with an eye toward inference to a population based on a sample. As they begin to formulate their own questions, they become aware that the world around them is filled with data that affect their own lives, and they begin to appreciate that statistics can help them make decisions based on data, logic and investigation, and not whim.
Level C

Background from Levels A and B

Levels A and B of the statistics guidelines introduce students to:

- Statistics as an investigatory process
- The importance of using data to answer appropriately framed questions
- Types of variables (categorical versus numerical)
- Graphical displays (bar graph, histogram, box plot, scatterplot)
- Numerical summaries (counts, proportions, mean, median, range, quartiles, interquartile range, correlation)
- Common designs of studies (census, simple random sample, randomized designs for experiments)
- The process of drawing conclusions from data
- The role of probability in statistical investigations

All of these ideas are revisited at Level C, but the types of studies emphasized here will be of a deeper statistical nature. Statistical studies at this level will require students to draw on basic concepts from earlier work, to extend the concepts to cover a wider scope of investigatory issues, and to develop a deeper understanding of inferential reasoning along with increased ability to explain that reasoning to others.

Objectives of Level C

At Level C, the emphasis will be on interpretation and the use of statistical methods to answer questions rather than on the mechanics of computing summary statistics or drawing graphs. In general, students should be able to

- Formulate questions that can be answered with data.
- Devise a reasonable plan for collecting appropriate data through observation, sampling or experimentation.
- Draw conclusions and use data to support these conclusions.
- Understand the role that variability plays in the decision making process.

Specifically, Level C includes recommendations on:

1. The Investigatory Process
   What is the question and how are data collected and analyzed to provide an answer?

2. Design of a Statistical Study
   Sample survey
   Experiment
   Observational study

3. Analysis of Data
   Mean and standard deviation
   Sampling distributions (through simulation)
Association (categorical variables)
Regression and correlation (measurement variables)

4. Interpretation: Statistical Inference
   Statistical Significance
   P-values
   Margin of Error

5. The Role of Probability
   Review of probability as essential to statistical inference
   Special role of the normal distribution

Getting Started

Data and stories that surround the data must be of interest to students! That is the main point to remember when teaching data analysis. The second point is that the data and stories must have enough depth to demonstrate the need for statistical thinking. The following example illustrates these points.

Students are interested in issues that affect their lives, and issues of health often fall into that category. News items are an excellent place to look for items of current interest, including items on health, and one health-related topic making lots of news lately is obesity. The following relates to a news story that is rich enough to provide a context for many of the statistical topics to be covered in a high school setting.

Obesity in America

A recent newspaper article begins with the following lines. “Ask anyone: Americans are getting fatter and fatter. Advertising campaigns say they are. So do federal officials and the scientists they rely on. … In 1991, 23 percent of Americans fell into the obese category; now 31 percent do, a more than 30 percent increase. But Dr. Jeffrey Friedman, an obesity researcher, at Rockefeller University, argues that contrary to popular opinion, national data do not show Americans growing uniformly fatter. Instead, he says, the statistics demonstrate clearly that while the very fat are getting fatter, thinner people have remained pretty much the same. … The average weight of the population has increased by just 7 to 10 pounds.” The discussion in the article refers to adults.

The following are suggested questions to explore with students who have a Level B background in statistics, but are moving on to Level C.

a. Sketch what you think a distribution of weights of American adults might have looked like in 1991. Adjust the sketch to show what the distribution of weights might look like today (actually, 2002). Before making your sketches, think about the shape, center and spread of your distributions. Will the distribution be skewed or symmetric? Will the median be smaller, larger or about the same size as the mean? Will the spread increase as you move from the 1991 distribution to the 2002 distribution?
b. Which sounds more newsworthy, “Obesity has increased by over 30%” or “On the average, the weight of Americans has increased by less than 10 pounds?” Explain your reasoning.

c. The title of the article is *The Fat Epidemic: He Says It’s an Illusion.* [See *New York Times*, June 8, 2004 or *Chance*, Vol. 17. No. 4, Fall 2004, p. 3 for the complete article.] Do you think this is a fair title? Explain your reasoning.

d. The data on which the percentages are based come from the National Center for Health Statistics, National Health and Nutrition Examination Survey (NHANES) 2002. This is survey of approximately 5800 residents of the U.S. Although the survey design is more complicated than a simple random sample, the margin of error calculated as if it were a simple random sample is a reasonable approximation. What is an approximate margin of error associated with the 31% estimate of obesity for 2004? Interpret this margin of error for a newspaper reader who never studied statistics.

Students should realize that a distribution of weights is going to be skewed toward the larger values (many are overweight but few are underweight). This generally produces a situation in which the mean is larger than the median. Because 8% shifted over the obesity line between 1991 and 2002, but the average weight (or center) did not shift very much, the upper tail of the distribution must have gotten “fatter,” indicating a larger spread for the 2002 data. Students will have a variety of interesting answers for parts (b) and (c). The role of the teacher is help students understand whether or not their answers are supported by the facts. Part (d) foreshadows a concept to be studied at Level C.

For the curious, here is how obesity is defined. “Body Mass Index (BMI) is a mathematical calculation used to determine whether a patient is overweight. BMI is calculated by dividing a person's body weight in kilograms by their height in meters squared (weight [kg] /height [m]^2) or by using the conversion with pounds (lbs) and inches (in) squared as shown below. This number can be misleading, however, for very muscular people, or for pregnant or lactating women.

\[
[\text{Weight (lbs)} \div \text{height (in)}^2] \times 704.5 = \text{BMI}
\]

Being obese and being overweight are not the same condition. A BMI of 30 or more is considered obese and a BMI between 25 to 29.9 is considered overweight.”
[Source: http://www.obesity.org/]

**The Investigatory Process**

As stated at the beginning of Level A, data are more than just numbers. **Students need to understand the types of questions that can be answered with data.** “Is the overall health of high school students declining in this country?” That is too big a question to answer by a statistical investigation (or even many statistical investigations). Certain
aspects of the health of students, however, can be investigated by formulating more specific questions like “What is the rate of obesity among high school students?”; “What is the average daily caloric intake for high school seniors?”; “Is a three-day-a-week exercise regimen enough to maintain heart rate and weight within acceptable limits?” Question formulation, then, becomes the starting point for a statistical investigation.

Most questions that can be answered through data collection and interpretation require data from a designed study, either a sample survey or an experiment. These two types of statistical investigations have some common elements, as each requires randomization both for purposes of reducing bias and building a foundation for statistical inference, and each makes use of the common inference mechanisms of margin of error in estimation and $p$-value in hypothesis testing (both to be explained later). But these two types of investigations have very different objectives and requirements. Sample surveys are used to estimate or make decisions about characteristics (parameters) of populations and a well-defined, fixed population is the main ingredient of such a study. Experiments are used to estimate or compare the effects of different experimental conditions, called treatments, and require well-defined treatments and experimental units on which to study those treatments.

Estimating the proportion of residents of a city that would support an increase in taxes for education requires a sample survey. If the selection of residents is random, then the results from the sample can be extended to represent the population from which the sample was selected. A measure of sampling error (margin of error) can be calculated to ascertain how far the estimate is likely to be from the true value. Testing to see if a new medication to improve breathing for asthma patients produces greater lung capacity than a standard medication requires an experiment in which a group of patients who have consented to participate in the study are randomly assigned to either the new or the standard medication. With this type of randomized comparative design, an investigator can determine, with a measured degree of uncertainty, whether or not the new medication caused an improvement in lung capacity. Randomized experiments are, in fact, the only type of statistical study capable of establishing cause and effect. Any generalization extends only to the types of units used in the experiment, however, as the experimental units are not usually sampled randomly from a larger population. To generalize to a larger class of experimental units, more experiments would have to be conducted. That is one reason why replication is a hallmark of good science.

Studies that have no random selection of sampling units or random assignment of treatments to experimental units are called observational studies in this document. A study of how many students in your high school have asthma and how this breaks down among gender and age groups would be of this type. Observational studies are not amenable to statistical inference in the usual sense of that term, but they can provide valuable insights on the distribution of measured values and the types of associations among variables that might be expected.

**Design of a Study**
Students should understand the key features of both sample surveys and experimental designs, including how to set up simple versions of both types of investigations, how to analyze the data appropriately (as the correct analysis is related to the design), and how to clearly and precisely state conclusions for these designed studies. Key elements of the design and implementation of data collection plans for these types of studies will be addressed here; the analysis and interpretation components will be addressed in the following two sections.

Sample Surveys

Students should understand that obtaining good results from a sample survey depends on four basic features - the population, the sample, the randomization process that connects the two, and the accuracy of the measurements made on the sampled elements. For example, to investigate a question on health of students, a survey might be planned for a high school. What is the population to be investigated? Is it all the students in the school (which changes on a daily basis)? Perhaps the questions of interest involve only juniors and seniors. Once the population is defined as precisely as possible, what is an appropriate sample size and how can a random sample be selected? Is there, for example, a list of student who can then be numbered for random selection? Once the sampled students are found, what questions are to be asked of them? Are the questions fair and unbiased (as far as possible) and can or will the students actually answer them accurately?

Two samples of size 50 from the same population of students will not give the same result on, say, the proportion of students who eat a healthy breakfast. This variation from sample to sample is called sampling error and this is the type of error that we can measure statistically. Other errors (or biases) that slip in because the sample was not a random sample to begin with, because the sample was selected from the wrong population, because a number of the students selected in the sample refused to participate, or because the questions were poorly written and the responses ambiguous, are not easily measured. These types of errors should be considered carefully before the study begins so that plans can be made to reduce them as far as possible.

Experiments

Students should understand that obtaining good results from an experiment depends upon four basic features - well-defined treatments, appropriate experimental units to which these treatments can be assigned, the randomization process that is used to assign treatments to experimental units, and accurate measurements of the results of the experiment. Experimental units generally are not randomly selected from a population of possible units. Rather, they are the ones that happen to be available for the study. In experiments with human subjects, the people involved have to sign an agreement stating that they are willing to participate in an experimental study. In experiments with agricultural crops, the experimental units are the field plots that happen to be available. In an industrial experiment on process improvement the units may be the production lines in operation in a given week.
As in the sample survey, variability due to the random assignment of treatments to experimental units can be measured statistically, but variability resulting from a poor design cannot. Suppose treatment A gets assigned to patients over the age of 60 and treatment B to patients under the age of 50. If the treatment responses differ, it is now impossible to tell whether the difference is due to the treatments themselves or the ages of the patients. (This kind of bias in experiments is called confounding.) The randomization process, if properly done, will usually balance treatment groups so that this type of bias is minimized.

**Observational Studies**

**Students should understand that observational studies are useful for suggesting patterns in data and relationships between variables, but do not provide a strong basis for estimating population parameters or establishing differences among treatments.** Asking the students in your room whether or not they eat a healthy breakfast is not going to help you establish the proportion of healthy breakfast eaters in the school because the students in your room may not be representative of the students in the school. Random sampling is the only way to be confident of a representative sample for statistical purposes. Similarly, feeding your cats diet A and your neighbors cats diet B is not going to allow you to claim that one diet is better than the other in terms of weight control because there was no random assignment of experimental units (cats) to treatments (diets), and as a consequence there may be many biasing or confounding variables. Studies of the type suggested above are merely observational; they may suggest patterns and relationships but they are not a reliable basis for statistical inference.

**Analysis of Data**

When analyzing data from well-designed sample surveys, students should understand that an appropriate analysis is one that can lead to justifiable inferential statements based on estimates of population parameters. The ability to draw conclusions about a population using information from a sample depends on information provided by the distribution (called the **sampling distribution**) of the sample statistic that is being used to summarize the sample data. The two most common statistics used in applications are the sample proportion for categorical data and the sample mean for measurement data. When the sample mean is the statistic of interest, the appropriate measure of spread (variation) in the sample is the sample standard deviation. Students should gain an understanding of the behavior of proportions, means and standard deviations through the practice of calculating and interpreting these summary statistics on many real data sets.

**Proportions**

Properties of the sampling distribution for a sample proportion can be illustrated quite simply by using random digits as a device to model various populations. Suppose a population is assumed to have 60% “successes” (\( p = .6 \)) and we are to take a random sample of \( n=40 \) cases from this population. How far can we expect the sample proportion
of successes to deviate from this population value? This can be answered by determining what the sampling distribution of sample proportions looks like through repeated selection of samples of 40 random digits (with replacement) from a population in which 6 of the ten digits from 0 to 9 are labeled “success” and 4 are not. A simulated distribution constructed using sample proportions from 200 different random samples of size 40 from a population with 60% successes is shown in Figure 1.

**FIGURE 1**

![Histogram of sample proportions](image)

Getting into the habit of using shape, center and spread to describe distributions, one can state that this simulated sampling distribution of sample proportions has a mound shape (approximately normal). Because the mean and standard deviation of the 200 sample proportions were .59 and .08 respectively, the simulated distribution shown in Figure 1 has a mean of .59 (very close to $p = .6$) and a standard deviation of .08. By studying this sampling distribution and others that can be generated the same way, students will see patterns emerge and will see that the sampling distributions for sample proportions center at $p$, the population proportion of “successes”, and that the standard deviations for the sampling distribution turns out to be approximately

$$\sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$$

where $\hat{p}$ is the observed sample proportion in a single sample. In addition, if the sample size is reasonably large, the shape of the sampling distribution is approximately normal.

A follow-up analysis of these simulated sampling distributions shows students that about 95% of the sample proportions lie within a distance of

$$2\sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$$

from the true value of $p$. This distance, sometimes called the **margin of error**, is useful in estimating where a population proportion might lie in relation to a sample proportion for a new study in which the true population proportion is not known.
Means

Properties of the sampling distribution for a sample mean can be illustrated in a similar way. Figure 2 shows the distribution of the sample mean when samples of 10 random digits are selected (with replacement). This models sampling from a population that has a uniform distribution with equal numbers of 0’s, 1’s, 2’s, and so on.

**FIGURE 2**

This distribution can be described as approximately normal with a mean of 4.53 (the mean of the 200 sample means from the simulation) and a standard deviation of 0.87 (the standard deviation of the 200 sample means). The population described has a mean of 4.5 and a standard deviation of 2.9. By studying this sampling distribution and others produced similarly students will see patterns and can see that the standard deviation of the sampling distribution for a sampling mean is approximately the population standard deviation divided by the square root of the sample size, in this case $2.9/\sqrt{10} = 0.92$.

The margin of error in estimating a population mean from a single random sample is approximately

$$2 \frac{s}{\sqrt{n}}$$

where $s$ denotes the sample standard deviation for the observed sample. The sample mean should be within this distance of the true population mean about 95% of the time in repeated random sampling.

Regression

Regression analysis refers to the study of relationships between variables. If the “cloud” of points in a scatterplot of paired numerical data has a linear shape, a straight line may be a realistic model of the relationship between the variables under study. The least squares line runs through the center (in some sense) of the cloud of points. Residuals are defined to be the deviations in the $y$ direction between the points in the scatterplot and the
least squares line; spread is now the variation around the least squares line, as measured by the standard deviation of the residuals. When using a fitted model to predict a value of $y$ from $x$, the margin of error depends on the standard deviation of the residuals.

**Interpretation: Statistical Inference**

**Inference from Samples**

The key to statistical inference is the sampling distribution of the sample statistic, which provides information on the population parameters being estimated or the treatment effects being tested. As described in the previous section, knowledge of the sampling distribution for a statistic, like a sample proportion or sample mean, leads to a margin of error that provides information about the maximum likely distance between a sample estimate and the population parameter being estimated. Another way to state this key concept of inference is that an estimator plus and minus the margin of error produces an interval of plausible values for the population parameter, any one of which could have produced the observed sample result as a reasonably likely outcome.

**Inference from Experiments**

Do the treatments differ? In analyzing experimental data this is one of the first questions asked. This question of difference is generally posed in terms of differences between the centers of the data distributions (although it could be posed as a difference between 90\textsuperscript{th} percentiles or any other measure of an aspect of a distribution). Because the mean is the most commonly used statistic for measuring center of a distribution, this question of differences is generally posed as a question about the differences in means. The analysis of experimental data, then, usually involves a comparison of means.

Unlike sample surveys, experiments do not depend on random samples from a fixed population. Instead, they require random assignment of treatments to pre-selected experimental units. The key question, then, is of the following form: “Could the observed difference in treatment means be due to the random assignment (chance) alone, or can it be attributed to the treatments administered?”

**Examples**

The following examples are designed to illustrate the points made above by carefully considering the four phases of a statistical analysis (question, design, analysis, interpretation) in a variety of real contexts.

**A Survey of Music Preferences**

**Question**
A survey of student music preferences was introduced at level A, where the analysis consisted of making counts of student responses and displaying the data in a bar graph. At level B the analysis was expanded to considering relative frequencies of preferences and cross-classified responses for two types of music displayed on a two-way table. The following survey questions were suggested:

What kinds of music do you like? A Survey

1. What kinds of music do you like?

   a. Do you like country music? Yes or No
   b. Do you like rap music? Yes or No
   c. Do you like rock music? Yes or No

2. Which of the following types of music do you like to most? Select only one.

   Country     Rap/Hip Hop     Rock

Design

It was proposed that the survey questions be asked of a representative sample of students from a school so that generalizations can be made to the school level. This could be accomplished by selecting a simple random sample of 50 students from the school. The results can then be generalized to the school (but not beyond) and the level C discussion will center on basic principles of generalization, or statistical inference.

Analysis

The level C analysis begins with a two-way table of counts that summarizes the data on two of the questions, “Do you like rock music?” and “Do you like rap music?” The table provides a way to examine the responses to each question separately as well as a way to explore possible connections (association) between the two categorical variables. The two-way table is shown in Table 1.

<table>
<thead>
<tr>
<th></th>
<th>Two -Way Frequency Table</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Like Rock Music?</td>
</tr>
<tr>
<td>Like Rap Music?</td>
<td></td>
</tr>
<tr>
<td>Yes</td>
<td>Yes: 25, No: 4, Row Total: 29</td>
</tr>
<tr>
<td>No</td>
<td>Yes: 6, No: 15, Row Total: 21</td>
</tr>
<tr>
<td>Column Totals</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Total: 31, 19, 50 = Grand Total</td>
</tr>
</tbody>
</table>
As demonstrated at level B, there are a variety of ways to interpret data summarized in a two-way table such as Table 1. Some examples based on all 50 students in the survey include:

- 25 of the 50 students (50%) liked both rap and rock music.
- 29 of the 50 students (58%) liked rap music.
- 19 of the 50 students (38%) did not like rock music.

One type of statistical inference relates to conjectures (hypotheses) made before the data were collected. Suppose a student says “I think more than 50% of the students in the school like rap music.” The statistical question is, then, do the sample data support this claim or not. One way to arrive at an answer is to set up a hypothetical population that has 50% successes (like even and odd digits produced by a random number generator) and repeatedly take samples of size 50 from it, each time recording the proportion of even digits. The sampling distribution of proportions so generated will be similar to the one in Figure 3.

**FIGURE 3**

Interpretation

A sample proportion greater than or equal to the observed .58 occurs 12 times out of 100. This suggests that the result of .58 is not very unusual in sampling from a population with .5 as the “true” proportion of students who like rap music, so there is little evidence to support the student’s claim. A value of .50 (or maybe even something smaller) is plausible based on what was observed in the sample. The fraction of times the observed result is matched or exceeded (.12 in this investigation) is called the approximate **p-value**. A small p-value would have supported the student’s claim.

Suppose another student hypothesized that only 40% of the students in the school like rap music. Now, the samples of size 50 must be repeatedly selected from a population that has 40% successes (like random digits with 1 through 4 representing success and the other digits representing failure). Figure 4 shows the results of one such simulation. The
observed result of .58 was reached only 1 time out of 100 (approximate p-value = .01). It is not likely that a population in which 40% of the students like rap music would have produced a sample proportion of 58% in a random sample of size 50. This student’s claim can be rejected!

**FIGURE 4**

Another way of stating the above is that .5 is a plausible value for the true population proportion, based on the sample evidence, but .4 is not. A set of plausible values can be found by using the margin of error, as explained previously. The margin of error is estimated to be about

\[ 2 \sqrt{\frac{\hat{p}(1-\hat{p})}{n}} = \sqrt{\frac{.58(.42)}{50}} = 0.14 \]

Thus, any population proportion between .58 − .14 = .44 and .58+.14=.72 can be considered a plausible value for the true proportion of students who like rap music. Notice that .5 is well within this interval but .4 is not.

**Question 2**

Another type of question to ask about the student preferences on music is of the form “Do those who like rock music also tend to like rap music?” In other words, is there an association between liking rock music and liking rap music?

**Design 2**

The same data from the random sample of 50 students is used to answer this question.

**Analysis 2**

According Table 1 a total of 31 students in survey liked rock music. Among those students, the proportion who also like rap music is (25/31) = .81. Among the 19 students who do not like rock music, 4/19 = .21 is the proportion who like rap music. The large difference between these two proportions (.60) suggests that most students who
like rock also like rap. There appears to be a strong association between liking rock music and liking rap music.

But could this association simply be due to chance (as introduced through the random sampling). If there were no association between the two groups the 31 students who like rock would behave as a random selection from the 50 in the sample. To simulate this situation we make up a population of 29 1’s (those who like rap) and 21 0’s (those who do not like rap) and mix them together. Then, we select 31 (representing those who like rock) at random and see how many 1’s (those who like rap) we get. It is this entry that goes into the (yes, yes) cell of the table, and from that data the difference in proportions can be calculated. Repeating the process many times produces a simulated sampling distribution for the difference between two proportions, as shown in Figure 5.

**FIGURE 5**

![Dot Plot](image.png)

Movable line is at 0.60

**Interpretation 2**

The observed difference of .6 was never reached in 100 trials, indicating that the observed difference cannot be attributed to chance alone. There is evidence of a real association between liking rock music and liking rap music.

**An Experiment on the Effects of Light on the Growth of Radish Seedlings**

**Question**

What is the effect of different lengths of light and dark on the growth of radish seedlings? This question was posed for a class of biology students who then set about designing and carrying out an experiment to investigate the question. All possible relative lengths of light to dark cannot possibly be investigated in one experiment, so the students decided to
focus the question on three treatments: 24 hours of light, 12 hours of light and 12 hours of darkness, and 24 hours of darkness. This covers the extreme cases and one in the middle.

Design

With the help of a teacher, the class decided to use plastic bags as "growth chambers." The plastic bags would permit the students to observe and measure the germination of the seeds without disturbing them. Two layers of moist paper towel were put into a disposable plastic bag, with a line stapled about 1/3 of the way from the bottom of the bag (side opposite opening) to hold the paper towel in place and provide a seam to hold the radish seeds in place for germination. Although three growth chambers would be sufficient to examine the three treatments, this class made four growth chambers with one designated for the 24 hours of light treatment, one for the 12 hours of light and 12 hours of darkness treatment, and two for the 24 hours of darkness treatment. One hundred twenty seeds were available for the study. Thirty of the seeds were chosen at random and placed along the stapled seam of the 24 hours of light bag. Thirty seeds were then chosen at random from the remaining 90 seeds and placed in the bag the 12 hours of light and 12 hours of darkness bag. Finally, 30 of the remaining 60 seeds were chosen at random and placed in one of the 24 hours of darkness bags and the final 30 seeds placed in the final bag. After three days, the lengths of radish seedlings for the germinating seeds were measured and recorded. These data are provided in Table 2; the measurements are in millimeters.

Analysis

The first step is to make a plot of the data to look for patterns and any unusual departures from pattern. Box plots are ideal for comparing data from more than one treatment, as you can see in Figure 6. Both the centers and the spreads increase as the amount of darkness increases. There are three outliers (one at 20mm and two at 21mm) in the Treatment 1 (24 hours of light) data. Otherwise, the distributions are fairly symmetric, which is good for statistical inference.

</tbody>
</table>

Experiments are designed to compare treatments, usually by comparing means. So, the original question on the effect of different lengths of light and dark on the growth of radish seedlings can be turned into two questions on treatment means. Is there evidence that 12 hours of light and 12 hours of dark (Treatment 2) has a higher mean than 24 hours of light (Treatment 1)? Is there evidence that 24 hours of dark (Treatment 3) has a higher mean than 12 hours of light and 12 hours of dark (Treatment 2)? Based on the box plots and the summary statistics, it looks like the means differ, but students should now realize that this casual observation can be verified by ruling out chance as a possible explanation. The Treatment 2 mean is 6.2 mm larger than the Treatment 1 mean. If there is no real difference between the two treatments, then the observed difference must be due to the random assignment of seeds to the bags; one bag was simply lucky enough to get a preponderance of good and lively seeds. But, if a difference this large (6.2 mm) is likely to be the result of randomization alone, then we should see differences of this magnitude quite often if we repeatedly re-randomize the measurements and calculate a new difference in observed means. This, however, is not the case, as is seen in Figure 7. This figure was produced by mixing the measurements from Treatments 1 and 2 together, randomly splitting them into two groups of 28 measurements each, recording the difference in means for the two groups, and repeating the process 200 times.

**FIGURE 7**

Interpretation

The observed difference of 6.2 mm was exceeded only one time in 200 tries, for an approximate p-value of 1/200. This is very small, and gives strong evidence to support the hypothesis that there is a real difference between the means for Treatments 1 and 2. The observed difference of 6.2 mm is very unlikely to be due simply to chance.
In a comparison of the means for Treatments 2 and 3 the same procedure is used, except that the combined measurements are split into groups of 28 and 58 each time. Again, the observed difference of 6 mm was exceeded only 1 time out of 200 trials (see Figure 8), giving strong evidence of a real difference between the means for Treatments 2 and 3. In summary, all three means show real differences that cannot be explained by the random assignment of seeds to the bags; the more hours of darkness, the greater the growth of the seedling, at least for these three light versus darkness times.

**FIGURE 8**

Students should be encouraged to go deeper into the interpretation, relating it to what is known about the phenomenon or issue under study. Why do the seedlings grow faster in the dark? Here is an explanation from a biology teacher. It seems to be an adaptation of plants to get the seedlings from the dark (under ground) where they germinate into the light (above ground) as quickly as possible. Obviously, the seedling cannot photosynthesize in the dark and is using up the energy stored in the seed to power the growth. Once the seedling is exposed to light it shifts its energy away from growing in length to producing chlorophyll and increasing the size of the leaves. These changes allow the plant to become self-sufficient and begin producing its own food. Even though the growth in length of the stem slows, the growth in diameter of the stem increases and the size of the leaves increases. Seedlings that continue to grow in the dark are spindly and yellow, with small yellow leaves. Seedlings grown in the light are a rich, green with large, thick leaves and short stems.

**Estimating the Density of the Earth – A Classical Study**

**Question**

What is the density of the earth? This is a question that intrigued the great scientist Henry Cavendish, who attempted to answer the question in 1798.
**Design**

Cavendish estimated the density of the earth by using the crude tools that were available to him at the time. He did not literally take a random sample; he measured on different days and at different times, as he was able. But, the density of the earth does not change over time, so his measurements can be thought of as a random sample of all the measurements he could have taken on this constant. The variation in the measurements is due to his measurement error, not to changes in the earth’s density. The earth’s density is the constant that is being estimated.

This is a typical example of an estimation problem that occurs in science. There is no real “population” of measurements that can be sampled; rather, the sample data is assumed to be a random selection from the conceptual population of all measurements that could have been selected. At this point there may be some confusion between an “experiment” and a “sample survey” because Cavendish actually conducted a scientific investigation to get his measurements. The key, however, is that he conducted essential the same investigation many times with a goal of estimating a constant, much like interviewing many people to estimate the proportion who favor a certain candidate for office. He did not randomly assign treatments to experimental units for the purpose of comparing treatment effects.

A famous Cavendish dataset contains his 29 measurements of the density of the earth, in grams per cubic centimeter. The data are shown below. [Source: http://lib.stat.cmu.edu/DASL/]

**TABLE 3: Densities of the Earth (grams per cubic centimeter)**

</tr>
<tr>
<td>5.44</td>
<td>5.39</td>
</tr>
</tbody>
</table>
**Analysis**

A look at the data is appropriate before proceeding with an analysis. The histogram below shows the data to be skewed toward the smaller values, with one unusually small value. If Cavendish were alive, you might check to see if that measurement might have been a mistake (and that is certainly what you should do for a current data set).

**FIGURE 9**

The mean of the 29 measurements is 5.420 and the standard deviation is 0.339. That makes the margin of error

\[
2 \frac{s}{\sqrt{n}} = 2 \frac{0.339}{\sqrt{29}} = 0.126
\]

**Interpretation**

The analysis shows that any value between 5.420-0.126 and 5.420+0.126, or in the interval (5.294, 5.546), is a plausible value of the density of the earth. That is, any value in the interval is consistent with the data obtained by Cavendish. Now, the questionable low observation should be taken into account as it will lower the mean and increase the standard deviation. If that measurement is regarded as a mistake and removed from the data set, the mean of the 28 remaining observations is 5.468 and the standard deviation is 0.222, producing a margin of error of 0.084 and an interval of plausible values of (5.384, 5.552). These are a little different, but the latter one better fits the statistical theory because it is based on a data set that is more “normal” looking.

Students can now check on how well Cavendish did; modern methods pretty much agree that the average density of the earth is about 5.515 grams per cubic centimeter. The great 18th century scientist did well!
**Height v. Forearm Length: Inference in Regression Modeling**

**Question**

Relationships among various physical features, such as height versus arm span and neck size versus shoe size, can be the basis of many interesting questions for student investigation. If I were painting a picture of a person, how could I get the relative sizes of the body parts correct? This question prompted students to carry out an investigation of one of the possible relationships, that between forearm length and height.

**Design**

The students responsible for the study sampled other students on which to make forearm and height measurements. Although the details are not clear on how the sample was actually selected, we will suppose that it is representative of students at the school and has the characteristics of a random sample. An important consideration here is to agree on the definition of “forearm” before beginning to take measurements. The data obtained by the students (in centimeters) is provided in Table 4.

</tr>
</tbody>
</table>
Analysis

A good first step in any analysis is to plot the data. These data are plotted in Figure 10. The linear trend apparent in the plot can be summarized by a least squares line (regression line) drawn through it, this one having slope 2.76 (cm in height per cm in forearm length) and an intercept of 45.8 cm. The residual plot shows how the departures from the regression line are arranged around zero.

**FIGURE 10**

```
<table>
<thead>
<tr>
<th>Forearm Length</th>
<th>Height</th>
</tr>
</thead>
<tbody>
<tr>
<td>39</td>
<td>155</td>
</tr>
<tr>

<td>160</td>
</tr>
<tr>
<td>41</td>
<td>165</td>
</tr>
<tr>
<td>42</td>
<td>170</td>
</tr>
<tr>
<td>43</td>
<td>175</td>
</tr>
<tr>
<td>44</td>
<td>180</td>
</tr>
<tr>
<td>45</td>
<td>185</td>
</tr>
<tr>
<td>46</td>
<td>190</td>
</tr>
</tbody>
</table>

Height = 2.76Forearm + 45.8; r^2 = 0.64
```

**Interpretation**

The linear trend is fairly strong, with a few large residuals but no unusual pattern in the residual plot. The slope (about 2.8 cm) can be interpreted as an estimate of the expected difference in heights for two persons whose forearms are 1 centimeter different in length. The intercept of 45.8 centimeters cannot be interpreted as the expected height of a person with a forearm zero centimeters long! However, the regression line can reasonably be used to predict the height of a person for whom the forearm length is known, as long as the known forearm length is in the range of the data used to develop the prediction equation (here 39 to 50 cm). The margin of error for this type of prediction is approximately 2(standard deviation of the residuals) = 2(5.8) = 11.6 mm. (There is no divisor of the square root of the sample size because you are predicting a single value instead of estimating a mean.)

Is the slope of 2.8 “real” or simply a result of the random selection process? If there were no trend in the data (positive or negative), then any of the height values could be paired with any of the forearm values with no loss of information. In the spirit of the
comparison of means in the radish experiment, you could then randomly mix up the heights (while leaving the forearm lengths as is), calculate a new slope, and repeat this process many times to see if the observed slope could be generated simply by randomization. The results of 200 such randomizations are shown in Figure 11. A slope as large as 2.8 is never reached by randomization, which provides strong evidence that the observed slope is not due simply to chance. An appropriate conclusion is that there is a positive association between forearm length and height.

**FIGURE 11**

![Slopes and Dot Plot](image)

**Comparing Mathematics Scores: An Observational Study**

Data is often presented to us in a form that does not call for much analysis, but does require some insight into statistical principles for correct interpretation. Test scores often fall into this category. Table 5 gives data on the state mean scores for the National Assessment of Educational Progress (NAEP) 2000 grade 4 mathematics scores for Louisiana and Kentucky. Even though these scores are based on a sample of students, these are the scores assigned to the states and consequently they can be considered observational data from that point of view.

**TABLE 5: NAEP 2000 Scores in Mathematics**

<table>
<thead>
<tr>
<th></th>
<th>Overall Mean</th>
<th>Mean for Whites</th>
<th>Mean for Nonwhites</th>
<th>Percent White</th>
</tr>
</thead>
<tbody>
<tr>
<td>Louisiana</td>

<td>229.51</td>
<td>204.94</td>
<td></td>
</tr>
<tr>
<td>Kentucky</td>
<td>220.99</td>
<td>224.17</td>
<td></td>
<td>87</td>
</tr>
</tbody>
</table>

To see if students understand the table, it is often informative to ask them to fill in a few omitted entries.

a. Fill in the two missing entries in the table. (53% and 199.71)
The more substantive questions involve the seeming contradictions that often occur in data of this type. The might be phrased as follows.

b. For the two states, compare the overall means. Compare the means for whites. Compare the means of nonwhites. What do you observe?

c. Explain why the reversals in direction take place once the means are separated into racial groups.

It is genuinely surprising to students that data summaries (means in this case) can go in one direction in the aggregate but can go in the opposite direction for each subcategory when disaggregated. This phenomenon is called Simpson’s paradox; students should see (and be required to find) many examples of it in real data.

**SAT Mathematics Scores v the Percentage Taking the Test: Association Between Quantitative Variables**

Table 6 gives observational data on the mean SAT math scores for the year 2000 versus the percentage of high school seniors taking the test for each of the states plus the District of Columbia. Important questions to explore may include the following.

a. Describe the relationship between the two variables.

b. Explain why the pattern you see here makes sense from a practical point of view.

Describing the relationship begins with a plot; the scatterplot of these data is shown in Figure 12.

Average SAT math scores by state versus percent of high school graduates who took the test [Source:College Board, 2000, http://www.collegeboard.org/press/senior00/html/tab1e3.html.]

FIGURE 12
Obviously, there is a pattern and it “goes downhill.” Students should be able to relate this to negative association; as one variable goes up, the other tends to go down. But, the discussion of pattern can go much deeper than “it goes downhill” to issues of linear trend versus curvature, clusters and gaps, and usual versus unusual data points. (Why is there a leveling off? Which states tend to cluster together?) As to why the pattern makes practical sense, students should be able to reason that as the percentage of students taking the test increases, so must the percentage of students with lesser academic interests and abilities.

**Observational Study – Toward Establishing Cause**

Observational studies are the only option for situations in which it is impossible or unethical to randomly assign treatments to subjects. Such situations are a common occurrence in the study of causes of diseases. A classical example from this field is the study of the relationship between smoking and lung cancer, a debate that was raging during the 1950’s and 1960’s. Society will not condone the notion of assigning some people to be smokers and others to be non-smokers in an experiment to see if smoking causes lung cancer. So, the evidence has to be gathered from observing the world as it is. But, the data collection process can still be designed in clever ways so as to obtain as much information as possible.

Here is an example from the smoking versus lung cancer debates. A group of 649 men with lung cancer were identified from a certain population in England. A control group of the same size was established by matching these patients with other men from the same population who did not have lung cancer. The matching was on background variables such as ethnicity, age and socio-economic status. (This is called a case-control study.) The objective, then, is to compare the rate of smoking among those with lung cancer to the rate for those without cancer.

**TABLE 7: Cigarette Smoking and Lung Cancer**
Lung cancer cases | Controls | Totals
---|---|---
Smokers | 647 | 622 | 1269
Non-smokers | 2 | 27 | 29

[Source: http://www-phm.umds.ac.uk/teaching/ClinEpid/ObservS.htm]

First, make sure the students understand the nature of the data in the table. Does this show, for example, that there was a very high percentage of smokers in England around 1950? The rate of smoking in these groups was (647/649)=.997 for the cancer patients and (622/649)=.958 for the controls. If these data had resulted from a random assignment or selection, the difference of about 4 percentage points would be statistically significant (by methods discussed earlier) and this gives the researcher reason to suspect that there is an association here that cannot be attributed to chance alone. Another way to look at these data is to think about randomly selecting one person from among the smokers and one person from among the non-smokers. The smoker has a chance of (647/1269)=.51 of being in the lung cancer column, while the non-smoker has only a (2/29)=.07 chance of being there. This is evidence of strong association between smoking and lung cancer, but it is not conclusive evidence that smoking was, in fact, the cause of the lung cancer. (This is a good place to have students speculate about other possible causes that could have resulted in data like these.)

Another step in establishing cause in observational studies is to see if the increase in exposure to the risk factor produces an increase in the disease. This was done with the same case-control study by looking at the level of smoking for each person, producing Table 8.

**TABLE 8: Level of Cigarette Smoking and Lung Cancer**

<table>

<td>84</td>
<td>0.67</td>
</tr>
</tbody>
</table>

The term “Probability” is used in the same sense as above. If a person is randomly selected from the 1-14 level, the chance that the person falls into the cancer column is .45, and so on for the other rows. The important result is that these “probabilities” increase with the level of smoking. This is evidence that an increase in exposure produces an increase in the disease rate.

Even with this additional evidence, students should understand that a cause and effect relationship is not established beyond a reasonable doubt. The main reason for this is that these observational studies are subject to bias in the selection of patients and controls. Another study of this type could have produced a different result. (As it turned out, many studies of this type produced remarkably similar results. That, coupled with laboratory
experiments on animals that established a biological link between smoking and lung cancer, eventually settled the issue for most people.)

**Observational Study – Rates over Time**

Vital statistics are a good example of observational data that are used every day by people in various walks of life. Most of these statistics are reported as rates, so an understanding of rates is a critical skill for high school graduates. The following table shows the death rates for sections of the population of the United States over a period of twelve years. Such sequences over time are often referred to as time series data.

**TABLE 9: United States Death Rates (deaths per 100,000 of population)**

</tr>
</tbody>
</table>

Students’ understanding of the rates can be established by posing problems such as:

a. Carefully explain the meaning of the number 1,029.1 in the lower left-hand data cell.

b. Give at least two reasons why the White Male and Black Male entries do not add up to the All Races male entry.

c. Can you tell how many people died in 2001 based on the above table alone?

Hopefully, they will quickly realize that they cannot change from rates of death to frequencies of deaths without knowledge of the population sizes. Table 10 provides the population sizes overall as well as for the male and female categories.

**TABLE 10: Population of the United States (in 1000’s)**
Year | Total persons | Male | Female
--- | --- | --- | ---
1990 | 249,623 | 121,714 | 127,909
1991 | 252,981 | 123,416 | 129,565
1992 | 256,514 | 125,247 | 131,267
1993 | 259,919 | 126,971 | 132,948
1994 | 263,126 | 128,597 | 134,528
1995 | 266,278 | 130,215 | 136,063
1996 | 269,394 | 131,807 | 137,587
1997 | 272,647 | 133,474 | 139,173
1998 | 275,854 | 135,130 | 140,724
1999 | 279,040 | 136,803 | 142,237
2000 | 282,224 | 138,470 | 143,755
2001 | 285,318 | 140,076 | 145,242

Noting that the population figures are in thousands but the rates are per 100,000, it takes a little thinking on a student’s part to realize that she can go from rates to counts for females by making the computation shown in the formula:

\[
\text{Female Deaths} = \text{Female Death Rate} \times \left( \frac{\text{Female Population}}{100} \right)
\]

Now, time series questions can be explored. For example, how does the pattern of female death rates over time compare to the pattern of actual female deaths? The plots of Figure 13 provide a visual impression. The death rates are trending down hill over time, with considerable variation, but the actual deaths are going up.

**FIGURE 13**
Students will discover that the picture for males is quite different, and this can lead to interesting discussions.

Observational studies, rates and time series data are all important concepts with which students should have experience.

The Appendix contains more examples of the types discussed in this section.

**The Role of Probability in Statistics**

Teachers and students must understand that statistics and probability are not the same thing. Statistics uses probability, much as physics uses calculus, but only certain aspects of probability make their way into statistics. The concepts of probability needed for introductory statistics (with emphasis on data analysis) include relative frequency interpretations of data, probability distributions as models of populations of measurements, an introduction to the normal distribution as a model for sampling distributions, and the basic ideas of expected value. Counting rules, most specialized distributions, and development of theorems on the mathematics of probability should be left to areas of discrete mathematics and/or calculus.

Understanding the reasoning and logic of statistical inference requires a basic understanding of some important ideas in probability. Students should be able to:

- Understand probability as a long-run relative frequency.
• Understand the concept of independence.
• Understand how probability can be used in making decisions and drawing conclusions.

In addition, because so many of the standard inferential procedures are based on the normal distribution, students should be able to evaluate probabilities using the normal distribution (preferably with the aid of technology).

Probability is an attempt to quantify uncertainty. The fact that, even though it is not possible to predict individual outcomes, the long-run behavior of a random process is predictable leads to the long-run relative frequency interpretation of probability. Students should be able to interpret the probability of an outcome as the proportion of the time, in the long run, that the outcome would occur. This long-run relative frequency interpretation of probability also provides the justification for using simulation to estimate probabilities. After observing a large number of chance outcomes, the observed proportion of occurrence for the outcome of interest can be used as an estimate of the relevant probability.

Students also need to understand the concept of independence. Two outcomes are independent if our assessment of the chance that one outcome occurs is not affected by knowledge that the other outcome has occurred. Particularly important to statistical inference is the notion of independence in sampling settings. Random selection (with replacement) from a population ensures that the observations in a sample are independent—for example, knowing the value of the third observation does not provide any information about the value of the fifth (or any other) observation. Many of the methods used to draw conclusions about a population based on data from a sample require the observations in a sample to be independent.

Most importantly, the concepts of probability play a critical role in developing statistical methods that make it possible to draw conclusions based on data from a sample and to assess the reliability of such conclusions.

To clarify the connection between data analysis and probability we will return to the key ideas presented in the inference section. Suppose an opinion poll shows 60% of sampled voters in favor of a proposed new law. A basic statistical question is, “How far might this sample proportion be from the true population proportion?” That the difference between the estimate and truth is less than the margin of error approximately 95% of the time is based on a probabilistic understanding of the sampling distribution of sample proportions. For large random samples, this relative frequency distribution of sample proportions is approximately normal. Thus, students should be familiar with how to use appropriate technology to find areas under the normal curve.

Suppose an experimenter divides subjects into two groups with one group receiving a new treatment for a disease and the other receiving a placebo. If the treatment group does better than the placebo group, a basic statistical question is, “Could the difference have been caused by chance alone?” Again, the randomization allows us to determine the probability of a difference being greater than that observed under the assumption of
no treatment effect, and this probability allows us to draw a meaningful conclusion from
the data. (A proposed model is rejected as implausible not primarily because the
probability of an observed outcome is small, but rather because it is in the tail of a
distribution.) Adequate answers to the above questions also require knowledge of the
context in which the underlying questions were asked and a “good” experimental design.
This reliance on context and design is one of the basic differences between statistics and
mathematics.

As demonstrated in the Analysis of Data section, it is known that the sampling
distribution of a sample mean will be approximately normal under random sampling, as
long as the sample size is reasonably large. The mean and standard deviation of this
distribution is usually unknown (introducing the need for inference) but sometimes these
parameter values can be determined from basic information about the population being
sampled. To compute these parameter values students will need some knowledge of
expected values, as demonstrated next.

According to the March 2000 Current Population Survey of the U.S. Census Bureau, the
distribution of family size is as given by the data Table 11. (A family is defined as two or
more related people living together. The number “7” really is the category “7 or more”,
but very few families are larger than 7.)

**TABLE 11: Family Size Distribution**

<tr>
<td>7</td>
<td>0.017</td>
</tr>
</tbody>
</table>

The first connection between data and probability to note is that these proportions (really
estimates from a very large sample survey) can be taken as approximate probabilities for
the next survey. In other words, if someone randomly selects a U.S. family for a new
survey, the probability that it will have 3 members is about .223.

The second point is that we can now find the mean and standard deviation of a random
variable (call it X) defined as the number of people in a randomly selected family. The
mean, sometimes called the expected value of X and denoted by E(X), is found by
formula

\[ E(X) = \sum x \cdot p(x) \]
which turns out to be 3.11 for this distribution. If the next survey contains 100 randomly selected families, then the survey is expected to produce 3.11 members per family, on the average, for a total of 311 people in the 100 families altogether.

The standard deviation of $X$, $SD(X)$, is the square root of the variance of $X$, $V(X)$, given by

$$V(X) = \sum [x - E(X)]^2 \cdot p(x)$$

For the family size data, $V(X)=1.54$ and $SD(X)=1.24$.

Thirdly, these facts can be assembled to describe the sampling distribution of the mean family size in a random sample of 100 families yet to be taken. That sampling distribution will be approximately normal in shape, centering at 3.11 with a standard deviation of $1.24/\sqrt{100} = 0.124$. This would be useful information for the person designing the next survey.

In short, the relative frequency definition of probability, the normal distribution, and the concept of expected value are the keys to understanding sampling distributions and statistical inference.

**Summary of Level C**

Students at Level C should become adept at using statistical tools as a natural part of the investigative process. Once an appropriate plan for collecting data has been implemented and the resulting data is in hand, the next step is usually to summarize the data using graphical displays and numerical summaries. At level C, students should be able to select summary techniques appropriate to the type of data available, construct these summaries, and describe in context the important characteristics of the data. Students will use the graphical and numerical summaries learned at Levels A and B, but should be able to provide a more sophisticated interpretation that integrates the context and the objectives of the study.

At Level C, students should also be able to draw conclusions from data and support these conclusions using statistical evidence. Students should see statistics as providing powerful tools that enable them to answer questions and to make informed decisions. But, students should also understand the limitations of conclusions based on data from sample surveys and experiments, and should be able to quantify uncertainty associated with these conclusions using margin of error and related properties of sampling distributions.

Appendix to Level A

What are Common Name Lengths?

Picture the Context and Formulate Questions

During the first week of school, a third-grade teacher is trying to help her students learn one another’s names by playing various games. During one of the games, a student named MacKenzie noticed that she and her classmate Zacharius each have 9 letters in their name. MacKenzie conjectured that their names were longer than everyone else’s names. The teacher decided that this observation by the student provided an excellent opening for a statistics lesson.

The next school day, the teacher reminds students of MacKenzie’s comment from the day before and asks the class what they would like to know about their classmates’ names. The class generates a list, which the teacher records on the board as follows:

- Who has the longest name? The shortest?
- Are there more 9 letter names or 6 letter names? How many more?
- What’s the most common name length?
- How many letters are in all of our names?
- If you put all of the 8 and 9 letter names together, will there be as many as the 5 letter names?

Collect Data

The statistics lesson begins with students writing their names on sticky notes and posting them on the white board at the front of the room. This is a census of the classroom because they are gathering data from all students in the class.

Given no direction about how to organize the notes, the students simply place them randomly on the board.

Analyze Data
In order to help students think about how to use graphical tools to analyze data, the teacher asks the students if they are able to answer any of the posed questions easily now by looking at the sticky notes, and the students say they cannot. The teacher then suggests that they think of ways to better organize the notes. A student suggests grouping the names according to how many letters are in each name.

The teacher again asks if they can easily answer the questions that are posed. The students say that they can answer some of the questions, but not easily. The teacher asks what they can do to make it easier to answer the questions. Because the students have been constructing graphs since kindergarten, they readily answer, “Make a graph!” The teacher then facilitates a discussion of what kind of graph they will make, and the class decides on a dot plot, given the fact that their names are already on sticky notes and given the available space on the board. Note that this display is not a bar graph because bar graphs are made when the data represent a categorical variable (such as favorite color). A dotplot is appropriate for a numerical variable such as the number of letters in a name.
The teacher then uses computer software to translate this information into a more abstract dot plot. This helps the students focus on the general shape of the data rather than on the particular names of the students.

![Number of Letters in Name](image)

Interpret Results

The teacher then facilitates a discussion of each question posed by the students, using the data displayed in the graph to answer the questions. Students also add appropriate labels and titles to the graph. The teacher helps students use the word “mode” to answer the question about the most common name length. She introduces the term “range” to help students answer the questions about shortest and longest names. Students visualize from the dotplot that there is variability in name length from individual to individual. The range gives a sense of the amount of variability in name length within the class.

The teacher then tells the students that there is another useful question they can answer from this data. Sometimes it is helpful to know “about how long most names are.” For instance, if you were making place cards for a luncheon, you might want to know how long the typical name is in order to decide which size of place cards to buy. The typical or average name length is called the mean. Another way to think of this is “If all of our names were the same length, how long would they be?” To illustrate this new idea, the teacher has students work in groups of 4, and each child takes a number of snap cubes so that the number of cubes is the number of letters in his/her name. Then all four children at
one table put all of their snap cubes in a pile in the middle of the table. They count how many cubes they have in total. Then they share the cubes fairly with each child taking one at a time until they are all gone or there are not enough left to share. They record how many cubes each child received. (Students at some tables are able to use fractions to show that, for example, when there are 2 cubes left each person could get 1/2 cube. At other tables the students simply leave the remaining 2 cubes undistributed.) The teacher then helps the students symbolize what they have done by using addition to reflect putting all of the cubes in the middle of the table and using division to reflect sharing the cubes fairly among everyone at the table. They attach the words “mean” and “average” to this idea.

Finally, the students are asked to transfer the data from the sticky notes on the board to their own graph. The class helps the teacher generate additional questions about the data that can be answered for homework. Because the students’ graphs look different, the next day the teacher will lead a discussion about the features of the various graphs the students have constructed and the pros and cons of each.

**Valentine’s Day and Candy Hearts**

**Picture the Context and Formulate Questions**

As Valentine’s Day approaches, a teacher decides to plan a lesson in which children will analyze the characteristics of a bag of candy hearts. To begin the lesson, the teacher holds up a large bag of candy hearts and asks the children what they know about them from prior experience. The children know that the hearts are different colors and that they have words on them. The teacher asks the children what they wonder about the bag of hearts she is holding. The children want to know how many hearts are in the bag, what they say, and whether there are a lot of pink hearts because most people like pink ones the best.
The teacher tells the children that they will be able to answer some of those questions about their own bag of candy.

**Collect Data**

Each child receives a small packet of candy hearts. Students are asked how they can sort their hearts, and the students suggest sorting them by color—a categorical variable. The teacher asks students what question this will help them answer, and the students readily recognize that this will tell them which color has the most candies in the bag.

![Image of candy hearts]

**Analyze Data**

After sorting the candies into piles and counting and recording the number of candies in each pile, the teacher guides the students to make a bar graph with their candies on a blank sheet of paper. The children construct individual bar graphs by lining up all of their pink candies, all of their white candies, etc. The teacher then provides a grid with color labels on the x-axis and numerical labels on the y-axis so that the students can transfer their data from the actual candies to a more permanent bar graph.
Interpret Results

After students construct their individual graphs using the candies as a guide, the teacher distributes a recording sheet on which each student records what color occurred the most frequently (the modal category) and how many of each color they had. This is followed by a class discussion in which the teacher highlights issues of variability. First, the students recognize that the number of each color varies within a package. Students also recognize that their packets of candy were not identical, noting that some students had no green hearts while others had no purple hearts. Some students had more pink hearts than any other color while other students had more white hear than any other color. At level A, students are acknowledging variability between packages – the concept of between group variability that will be explored in more detail at level B. The students hypothesize that these variations in packages were due to how the candies were packed by machines. The students also noted differences in the total number of candies per packet but found this difference to be small. The student with the fewest candies had 12 while the student with the greatest number of candies had 15. The teacher asked students if they had ever read the phrase “packed by weight, not by volume” on the side of a package. The class then discussed what this meant and how it might relate to the number of candies in a bag.

(Note: Images in this example taken from http://www.littlegiraffes.com/valentines.html.)
APPENDIX TO LEVEL C

A Survey of Healthy Lifestyles

A high school class interested in healthy lifestyles carried out a survey to investigate various questions they thought were related to that issue. A random sample of 50 students selected from those attending a high school on a particular day were asked a variety of health related questions, including these two:

1. Do you think you have a healthy lifestyle?
2. Do you eat breakfast at least three times a week?

The data are given in Table 1.

TABLE 1: Results of lifestyle questions

<table>
<thead>
<tr>
<th>Healthy Lifestyle</th>
<th>Eat Breakfast</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Yes</td>
<td>19</td>
<td>34</td>
</tr>
<tr>
<td>No</td>
<td>5</td>
<td>16</td>
</tr>
<tr>
<td>Total</td>
<td>24</td>
<td>50</td>
</tr>
</tbody>
</table>

From these data, collected in well-designed sample survey, it is possible to estimate the proportion of students in the school who think they have a healthy lifestyle and the proportion who eat breakfast at least three times a week. It is also possible to assess the degree of association between these two categorical variables.

For example, in the lifestyle survey previously described, 24 students in a random sample of 50 students attending a particular high school reported that they eat breakfast at least three times per week. Based on this sample survey, it is estimated that the proportion of students at this school who eat breakfast at least three times per week to be \( \frac{24}{50} = 0.48 \) with a margin of error of

\[
2 \sqrt{\frac{(0.48)(0.52)}{50}} = 0.14
\]

Using the margin of error result from above (0.14), the interval of plausible values for the population proportion of students who eat breakfast at least three times a week is (0.34, 0.62). Any population proportion in this interval is consistent with the sample data in the sense that the sample result could reasonably have come from a population having this proportion of students eating breakfast.

To see if the answers to the breakfast and lifestyle questions are associated with each other you can compare the proportions of yes answers to the healthy lifestyle question for those who regularly eat breakfast with those who do not, much like the comparison of means for a randomized experiment. In fact, if a 1 is recorded for each yes answer and a 0 for each no answer, the sample proportion of yes answers is precisely the sample mean. For the observed data, there are a total of 34 1’s and 16 0’s. Re-randomizing these 50
observations to the groups of size 24 and 26 (corresponding to the yes and no groups on the breakfast question) and calculating the difference in the resulting proportions gave the results in Figure 1. The observed difference in sample proportions of \((19/24) - (15/26) = 0.21\) was matched or exceeded 13 times out of 200 runs, for an estimated probability of 0.065. This is moderately small, so there is some evidence that the two sample proportions differ. In other words, the responses to the health lifestyle question and the eating breakfast question appear to be related in the sense that those who think they have a healthy lifestyle also have a tendency to eat breakfast regularly.

**FIGURE 1**

An Experimental Investigation of Pulse Rates

On another health-related issue, a student decided to answer the question of whether or not simply standing for a few minutes increases the pulse (heart rate) by an appreciable amount. Subjects available for the study were the 15 students in a particular class. The “sit” treatment was randomly assigned to eight of the students; the remaining seven were assigned the “stand” treatment. The measurement recorded was a pulse count for 30 seconds, which was then doubled to approximate a one-minute count. The data, arranged by treatment, are in Table 3. From these data it is possible to either test the hypothesis that standing does not increase pulse rate, on the average, or to estimate the difference in mean pulse between those who stand and those who sit. The random assignment to treatments is intended to balance out the unmeasured and uncontrolled variables that could affect the results, such as gender and health conditions. This is called a completely randomized design.

**TABLE 2**
But, randomly assigning 15 students to two groups may not be the best way to balance background information that could affect results. It may be better to block on a variable related to pulse. Since people have different resting pulse rates, the students in the experiment were paired on resting pulse rate by pairing the two students with the lowest resting pulse rate, then the two next lowest, and so on. One person in each pair was randomly assigned to sit and the other to stand. The matched pairs data are in Table 3. As in the completely randomized design, the mean difference between sitting and standing pulse rate can be estimated. The main advantage of the blocking is that the variation in the differences (which now form the basis of the analysis) is much less than the variation among the pulse measurements that form the basis of analysis for the completely randomized design.

**TABLE 3**
In the first pulse rate experiment (Table 2) the treatments of “sit” or “stand” were randomly assigned to students. If there is no real difference in pulse rates for these two treatments, then the observed difference in means (4.1 beats per minute) is due to the randomization process itself. To check this out the data resulting from the experiment can be re-randomized (reassigned to sit or stand after the fact) and a new difference in means recorded. Doing the re-randomization many times will generate a distribution of differences in sample means due to chance alone and one can assess the likelihood of the original observed difference. Figure 2 shows the results of 200 such re-randomizations. The observed difference of 4.1 was matched or exceeded 48 times, which gives a probability of 0.24 of seeing a result of 4.1 or greater by chance alone. Because this is a fairly large probability, it can be concluded that there is little evidence of any real difference in means pulse rates between the sitting and the standing positions based on the observed data.

**FIGURE 2**
In the matched pairs design the randomization occurs within each pair, one person randomly assigned to sit while the other stands. To assess whether the observed difference could be due to chance alone and not due to treatment differences, the re-randomization must occur within the pairs. This implies that the re-randomization is merely a matter of randomly assigning a plus or minus sign to the numerical values of the observed differences. Figure 3 shows the distribution of the mean differences for 200 such re-randomizations; the observed mean difference of 5.14 was matched or exceeded 8 times. Thus, the estimated probability of getting a mean difference of 5.1 or larger by chance alone is 0.04. This very small probability provides evidence that the mean difference must be caused by something other than chance (induced by the initial randomization process) alone. A better explanation is that standing increases mean pulse rate over the sitting rate. The mean difference shows up as significant here, while it did not for the completely randomized design, because the matching reduced the variability. The differences in the matched pairs design have less variability than the individual measurements in the completely randomized design, making it easier to detect a difference in mean pulse for the two treatments.

**FIGURE 3**

Movable line is at 5.1

**Modeling the Dissolve Time of Alka Seltzer: Transformations of Data**

Some experiments lead to modeling the relationship between two variables, instead of testing hypotheses or estimating population or treatment means. Such an experiment is a study of the dissolve time of Alka Seltzer tablets carried out by a group of science students. Their question was “What is the relationship between the temperature of the water and the dissolve time of an Alka Seltzer tablet?” The students heated cups of water to various temperatures (centigrade) and then randomly choose a tablet to drop into the water. The measurement of interest was the time (seconds) until the tablet was completely dissolved. The data from the experiment is in Table 4 and the scatterplot of
the data is in Figure 4. It is obvious that the dissolve time decreases with increasing
temperature of the water, but the curvature in the pattern makes the actual relationship
between time and temperature somewhat challenging to model. A transformation is in
order if techniques of simple linear regression analysis are to be used.

</table>
In modeling the relationship between the time for an Alka Seltzer tablet to dissolve and the temperature of the water (see Figure 4) it is observed that the relationship is more complicated than a simple straight line. Straightening out this relationship requires a transformation of one or both variables; either the extreme temperatures need to be reduced or the extreme times need to be reduced, or both. It turns out that a logarithmic transformation on both variables works well, as shown in Figure 5. The equation of the least squares line is given under the figure. The slope of -0.76 indicates that the ln(time) will decrease, on the average, 0.76 units for every one unit increase in ln(temp). The residual plot shows no strong pattern (although there may still be some curvature here) and the correlation of -0.88 (negative square root of 0.77) shows a fairly strong relationship between the two variables. The standard deviation of the residuals is 0.32, which indicates that a prediction of ln(time) for a new situation with known ln(temp) would have a margin of error of approximately 2(0.32)= 0.64 units.
Problems in Quantitative Reasoning

The following examples are written as problems to present to students for their investigation.

P1. Frequency Tables; Relative Frequency and Association

I. The Teenage Attitudes and Practices Survey obtained completed questionnaires, either by telephone or mail, from a randomly selected group of 9965 12-18 year olds living in households across the country. One type of question asked the teenagers being interviewed about the perceived behavior of their peers. The teenagers answering the questions are classified as

NS = Never smoked
EX = Experimented with smoking
FS = Former smoker
CS = Current smoker

One question was "Do your peers care about keeping their weight down?" The data in the table are the population projections (in thousands) calculated from the sample responses.

<table>
<thead>
<tr>
<th></th>
<th>NS</th>
<th>EX</th>
<th>FS</th>
<th>CS</th>
</tr>
</thead>
<tbody>
<tr>
<td>A lot</td>
<td>6297</td>
<td>3613</td>
<td>197</td>
<td>2114</td>
</tr>
<tr>
<td>Somewhat</td>
<td>2882</td>
<td>1677</td>
<td>90</td>
<td>793</td>
</tr>
<tr>
<td>A little</td>
<td>1441</td>
<td>625</td>
<td>16</td>
<td>354</td>
</tr>
<tr>
<td>Don’t care</td>
<td>1709</td>
<td>822</td>
<td>33</td>
<td>377</td>
</tr>
</tbody>
</table>
a. Why would a question be formed in terms of peer behavior rather than as a direct question to the person being interviewed?

b. Approximately how many teenagers in the United States never smoked (as of 1989)?

c. What proportion of teenagers think their peers care a lot about keeping their weight down?

d. Approximately how many teenagers are current smokers in the United States? What proportion of them think their peers care a lot about keeping their weight down?

e. Among those that care a lot about keeping their weight down, what proportion have never smoked? What proportion are current smokers?

f. Do you think perceived peer attitudes toward keeping weight down are associated with smoking status of the teenager? Calculate appropriate proportions to justify your answer.

II. Another question on the survey of teenagers was "Do your peers care about staying away from marijuana?" The population projected frequencies (in thousands) are as follows:

<table>
<thead>
<tr>
<th>Care about staying away from marijuana</th>
<th>NS</th>
<th>EX</th>
<th>FS</th>
<th>CS</th>
</tr>
</thead>
<tbody>
<tr>
<td>A lot</td>
<td>7213</td>
<td>2693</td>
<td>75</td>
<td>857</td>
</tr>
<tr>
<td>Somewhat</td>
<td>2482</td>
<td>1861</td>
<td>109</td>
<td>1102</td>
</tr>
<tr>
<td>A little</td>
<td>744</td>
<td>542</td>
<td>27</td>
<td>298</td>
</tr>
<tr>
<td>Don’t care</td>
<td>1878</td>
<td>1550</td>
<td>119</td>
<td>1312</td>
</tr>
</tbody>
</table>

a. What proportion of those who never smoked think their peers care a lot about staying away from marijuana?

b. What proportion of the current smokers think their peers care a lot about staying away from marijuana?

c. Among those who think their peers care a lot about staying away from marijuana, what proportion have never smoked?

d. Among those who think their peers don't care about staying away from marijuana, what proportion have never smoked?

e. Do you think perceived peer attitudes toward staying away from marijuana are associated with smoking status of the teenager? What proportions help justify your answer?

P2. Sampling Distributions
A candidate in a two-party election randomly samples 100 voters and finds that only 45 favor him. Is it plausible that a majority of the voters in the population being sampled actually favor this candidate?

Possible answer: Simulate the sampling distribution for a sample proportion with sample size 100 and 50% “successes”. This is easy to do on a graphing calculator or computer. The display shows one set of 200 runs. The observed result of 45% is reasonable likely even if the true proportion is 50% (or slightly more).

![Sample Proportions Dot Plot]

**P3. Bivariate Data; Scatterplots, Linear Trends and Influence**

Major league baseball team owners pay big money for good hitters. But, how is percentage of wins related to batting average? Data for all major league teams from the 2001 season is provided in the accompanying table. Analyze and discuss the relationship between percentage of wins and batting average for (a) all teams, (b) the American League, and (c) the National League.

</table>

One possible discussion follows.

a. The analyses for all teams of the relationship between *batting average* and *percent wins* is shown below. The plot shows two teams, one in each league (Colorado and Seattle again) that may have undue influence on the analysis. With these teams in the picture, the linear trend is significant and shows a 3.72 percentage point increase in wins for each one-point increase in team batting average. (If the two influential points are removed, the result is an increase of 4.5 percentage points per unit increase in batting.)
b. For the American League, the average increase in percent wins jumps way up to 7.2 per one-point increase in batting average. But, Seattle is having tremendous influence here, and if this team is dropped the average increase drops to 5.3.

\[
\text{Percent\_Wins} = 7.22 \times \text{BattingAverage} - 1420; r^2 = 0.50
\]
The analysis for the National League is shown below. Colorado has tremendous influence in the opposite direction from the general trend. With Colorado, the data show no significant trend. Without Colorado, the slope jumps to an estimated 5.8 increase in percent wins for each one-point increase in batting average. So, without the influential points the two leagues exhibit about the same trends, but the American League shows greater variability in winning percentages.

![Baseball Scatter Plot](image)

**Percent_Wins = 1.77BattingAverage + 35; r^2 = 0.092**

The two plots below show the slopes of the regression lines for the two Leagues with and then without the influential points of Colorado and Seattle.

**All Teams** (The steeper line through the squares represents the American League.)
All teams except Colorado and Seattle (The lower line through the squares represents the American League.)

P4. Graphs: Distortions of Reality?

Study the graph pictured below. Do you see any weaknesses in this graphic presentation? If so, describe them and explain how they could be corrected.
Here are some plausible plots to correct errors of interpretation – and to raise other questions. Better presentations begin with a data table, …

<table>
<thead>
<tr>
<th>Year</th>
<th>Total Students</th>
<th>African American</th>
</tr>
</thead>
<tbody>
<tr>
<td>1996</td>
<td>29404</td>
<td>2003</td>
</tr>
<tr>
<td>1997</td>
<td>29693</td>
<td>1906</td>
</tr>
<tr>
<td>1998</td>
<td>30009</td>
<td>1871</td>
</tr>
<tr>
<td>1999</td>
<td>30912</td>

<td>33405</td>
<td>1845</td>
</tr>
</tbody>
</table>

and then go to more standard graphic displays of such data. The plot below shows total and African American enrollments on the same scale. When viewed this way one can see that the latter is a small part of the former, with little change, by comparison, over the years.
By viewing African American enrollments by themselves, one can see that the marked decrease between 1996 and 2002 may be turning around – or leveling off.

But, the ratio of African American to total enrollment is still on the decrease!
